Medical and Surgical Management

THE SPINE

Medical and Surgical Management

Vol. 1 & 2

Editors

Alexander R Vaccaro MD PhD MBA
Richard H Rothman Professor and Chairman
Department of Orthopedic Surgery
Professor of Neurosurgery
Co-Chief of Spine Surgery Sidney, Kimmel
Medical Center at
Thomas Jefferson University
Co-Director, Delaware Valley Spinal Cord
Injury Center
President, Rothman Institute
Philadelphia, Pennsylvania, USA

Brian W Su MD
Spine Surgeon, Medical Director
Spine Surgery
Marin General Hospital, Marin
Surgeon-in-Chief
California Orthopedics and Spine
Larkspur, California, USA

Kazuhiro Chiba MD PhD
Professor and Chairman
Department of Orthopedic Surgery
National Defense Medical College
Saitama, Japan

Marcel F Dvorak MD FRCSC MBA
Associate Senior Medical Director
Vancouver Acute, Vancouver General
Hospital and Vancouver Coastal Health
Professor, Department of Orthopedics
University of British Columbia
Vancouver, Canada

H Michael Mayer MD PhD
Professor, Department of Neurosurgery
Chairman, Spine Center
Schön Klinik München Harlaching
FIFA Medical Center of Excellence
Academic Hospital
Paracelsus Medical University Salzburg
München, Germany

S Rajasekaran
MS DNB FRCS (Ed) MCh (Liv) FACS
FRCS (Eng) PhD
Chairman
Department of Orthopedics
Trauma and Spine Surgery
Ganga Hospital
Coimbatore, Tamil Nadu, India

Luiz R Vialle MD PhD
Professor of Orthopedics
School of Medicine, Spine Unit
Cajuru University Hospital and
Marcelino Champagnat Hospital
Director, Musculoskeletal Tissue Bank
Pontifical Catholic University of
Paraná State, Curitiba, Brazil

Yan Wang MD
Professor and Chief Surgeon
301 Spine Center, Beijing
President, Chinese Academy of
Orthopedic Surgeons (CAOS)
Chairman, Chinese Spine Society
Deputy-Editor, SPINE Journal
(Wolters Kluwer)
Chinese PLA General Hospital
(301 Hospital), Beijing, China

Magdy Gamal Youssef MD
Professor
Department of Spine Surgery
Ain Shams University
Cairo, Egypt

Foreword

Robert Gunzburg MD PhD

The views and opinions expressed in this book are solely those of the original contributor(s)/author(s) and do not necessarily represent those of editor(s) of the book.

All rights reserved. No part of this publication may be reproduced, stored or transmitted in any form or by any means, electronic, mechanical, photocopying, recording or otherwise, without the prior permission in writing of the publishers.

All brand names and product names used in this book are trade names, service marks, trademarks or registered trademarks of their respective owners. The publisher is not associated with any product or vendor mentioned in this book.

Medical knowledge and practice change constantly. This book is designed to provide accurate, authoritative information about the subject matter in question. However, readers are advised to check the most current information available on procedures included and check information from the manufacturer of each product to be administered, to verify the recommended dose, formula, method and duration of administration, adverse effects and contraindications. It is the responsibility of the practitioner to take all appropriate safety precautions. Neither the publisher nor the author(s)/editor(s) assume any liability for any injury and/or damage to persons or property arising from or related to use of material in this book.

This book is sold on the understanding that the publisher is not engaged in providing professional medical services. If such advice or services are required, the services of a competent medical professional should be sought.

Every effort has been made where necessary to contact holders of copyright to obtain permission to reproduce copyright material. If any have been inadvertently overlooked, the publisher will be pleased to make the necessary arrangements at the first opportunity.

Inquiries for bulk sales may be solicited at: jaypee@jaypeebrothers.com

The Spine: Medical and Surgical Management (Vol 1)

First Edition: 2019

ISBN 978-93-5152-494-6

Printed at

Dedicated to

My daughter Mia who makes my wife and I beam with joy every day and wish we could spend all the time in the world with her.

Alexander R Vaccaro

My parents who taught me the definition of determination, my loving wife Thomasina, and my mentors Drs Alexander R Vaccaro and Robert Byers.

Brian W Su

My mentors, fellow colleagues, and most of all to my wife, Mari.

Kazuhiro Chiba

My wife, Sue.

Marcel F Dvorak

My teachers and patients and most of all to Isabel, Lukas and Frizzi.

H Michael Mayer

My parents, my brother and my wife Rama and children for their continuous guidance, support, encouragement and love.

S Rajasekaran

My wife, Elizabeth, always supporting my academic carrier, even when there was some non-sense...

Luiz R Vialle

My mentor Professor Shengxiu Zhu who taught and guided me to start my orthopedic career.

Yan Wang

My mentors, fellow colleagues and students at Ain-Shams University, all my colleagues who shared writing, editing and releasing this book, and most of all to my father and rest of my family and kids and a special dedication to my country.

Magdy Gamal Youssef

Editors' Biography

Alexander R Vaccaro graduated Summa Cum Laude from Boston College and received his medical degree from Georgetown University School of Medicine. He completed his internship at Cedars-Sinai Medical Center in Los Angeles, California, orthopedic surgery residency at Thomas Jefferson University in Philadelphia, and a spine fellowship at the University of San Diego, California, USA. He earned a PhD in spinal trauma and an MBA at the Fox School of Business at Temple University in Philadelphia. He is Chairman of Orthopedic Surgery and Professor of Neurosurgery at the Sidney Kimmel Medical College of Thomas Jefferson University. He is the past president of the American Spinal Injury Association and the Association for Collaborative Spine Research. Dr Vaccaro is Editor-in-Chief of Clinical Spine Surgery and is the Co-Director of the Regional Spinal Cord Injury Center of

the Delaware Valley and Co-Chief of Spine Surgery and the spine fellowship program at the Sidney Kimmel Medical College at Thomas Jefferson University, Philadelphia, Pennsylvania, USA.

Brian W Su graduated Tau Beta Pi from Duke University's School of Engineering with a degree in both biomedical and electrical engineering. He received his medical degree from Columbia University's College of Physicians and Surgeons. Dr Su completed orthopedic surgery residency at Columbia University's New York Orthopedic Hospital-New York Presbyterian Hospital and an orthopedic and neurosurgical spine fellowship at the Rothman Institute at Thomas Jefferson University Hospital. He serves as Medical Director of Spine Surgery at Marin General Hospital and Surgeon-in-Chief of California Orthopedics and Spine, Larkspur, California, USA. Dr Su is a founding member of the nation's first undergraduate research journal and was one of the youngest scientists to be principal investigator on a grant from the National Science Foundation. He is a reviewer for Spine, Clinical Spine

Surgery, and the Global Spine Journal and serves on committees for the Cervical Spine Research Society and North American Spine Society.

Kazuhiro Chiba graduated from the Keio University School of Medicine in Tokyo, Japan in 1983 and completed his residency and spine fellowship at the department of orthopedic surgery, Keio University, and affiliated hospitals. After earning a PhD, he became a postdoctoral fellow at the departments of orthopedic surgery and biochemistry at Rush Medical College in Chicago in 1994 and a year later, was appointed as a visiting Assistant Professor. He returned to Keio University in 1997 and was appointed as an Assistant Professor in 1999, Associate Professor in 2004, and Chairman in 2009. In 2013, he became Associate Director and Clinical Professor at Kitasato University, Kitasato Institute Hospital. He is currently Professor and Chairman of the Department of Orthopedic Surgery, National Defense Medical College in Saitama, Japan. His specialty includes degenerative conditions in the cervical, thoracic, and

lumbar spine. He also has expertise in basic science including biochemistry, molecular biology, and genetics of the intervertebral disc.

Marcel F Dvorak completed two years of an undergraduate degree at the University of Toronto and received his medical degree from the University of Ottawa. He completed an orthopedic residency at the University of British Columbia. Dr Dvorak is an Orthopedic Spine Surgeon at Vancouver General Hospital and a full time Professor of Orthopedics at the University of British Columbia. His surgical specialty is in the areas of adult spine deformity surgery, spinal trauma and spinal cord injury. He holds the Cordula and Gunter Paetzold Chair of Clinical Spinal Cord Injury Research and was the Scientific Director of the Rick Hansen Institute and Division Head of Spine at University of British Columbia and Vancouver General Hospital. In January 2017, Dr Dvorak completed his EMBA at the Ivey School of Business at Western University and he is currently the Associate Senior Medical Director at

Vancouver Acute, Vancouver Coastal Health, Vancouver, British Columbia, Canada.

H Michael Mayer graduated from Medical School at Johannes-Gutenberg-University in Mainz, Germany and earned his MD degree 'magna cum laude' in the same year. He completed his neurosurgical training at Free University of Berlin where he became a board certified neurosurgeon and then completed orthopedic training to become a board certified orthopedic surgeon in 1994. He also earned a PhD in neurosurgery and became Senior Lecturer and Assistant Professor at the Free University of Berlin. Since 1998, he has been the Head of the Spine Center at Schoen Klinik Muenchen Harlaching and since 2005, Honorary Professor of Neurosurgery at the Paracelsus Medical School Salzburg, Austria. In 2006, he became President of the EuroSpine, The Spine Society of Europe, as well as the founding president of the German Spine Society. He is an honorary member of the South African

Spine Society and is currently Deputy Editor of the Global Spine Journal. His surgical focus is on minimally invasive surgery, spine arthroplasty and spine problems in high-level athletes.

S Rajasekaran is Chairman of the Department of Orthopedics, Trauma and Spine Surgery, at the Ganga Hospital in Coimbatore, Tamil Nadu, India. He is the current President of SICOT, President of CSRS-AP, and Chair of the International Research Commission, AOSpine. He has previously served as President of the International Society of the Study of Lumbar Spine, Association of Spine Surgeons of India, Indian Orthopaedic Association and World Orthopedic Concern. He was the Hunterian Professor of the Royal College of Surgeons of England in 2012. His research interests relate to disc biology and nutrition, genetic and proteomic analysis of disc degeneration imaging of spinal cord injuries. He has won the prestigious ISSLS prize for spine research four times and the 'EuroSpine open paper award' in 2008.

Luiz R Vialle received his medical degree from the Pontifical Catholic University of the Paraná State, in Curitiba, Brazil. His orthopedic residency and spine training was completed at the Santa Casa Hospital in São Paulo, Brazil and Italian Hospital, Buenos Aires, Argentina. He completed his master's degree and PhD at the Federal University of Parana. He was the founder and past president of the Brazilian Spine Society and past president of AOSpine International. He is a Spine Surgeon in Curitiba, Professor of Orthopedics at the School of Medicine, Head of the Spine Unit of the University Hospitals, and Director of the Bone Section of the Human Tissue Bank, all from Pontifical Catholic University. His specialties include trauma, adult deformity and degenerative conditions.

Yan Wang graduated from The Second Military Medical University in Shanghai and earned his medical degree at the Chinese PLA Medical School in Beijing. He completed his internship and orthopedic surgery residency at the Chinese PLA General Hospital (301 Hospital) in Beijing, China. He is the Chief Surgeon of the 301 Orthopedic Hospital. Dr Wang is President of the Chinese Academy of Orthopedic Surgeons, Chairman of the Chinese Spine Society, and Deputy Editor of Spine Journal. He is the national representative for the Scoliosis Research Society and an active member of the North American Spine Society and the Association of Bone and Joint Surgeons. Dr Wang is also the past president of the Chinese Orthopedic Association.

Magdy Gamal Youssef received his medical degree from Ain-Shams University Hospital in Cairo, Egypt. Ain-Shams is one of the highest ranked universities in the Middle East. He completed his orthopedic residency and spine surgery training at Ain-Shams University. He also received a master's and medical degree in spine surgery and became a Lecturer in the Orthopedic Department at Ain-Shams University. Dr Youssef completed a spine fellowship at Nottingham Spine Center with a focus on spinal deformities. He is currently Professor of Spine Surgery at Ain-Shams University and is the Head of the Spine Unit at the International Medical Center. He is a member of many spine societies; the North American Spine Society, EuroSpine, SMISS and AOSpine. His areas of interest include transforaminal endoscopic spine surgery, deformities, and degenerative spine conditions.

Foreword

It is refreshing in this time of ever faster electronic flowing of information, to see some people still take the time to sit back, relax and reflect about what keeps us all professionally busy.

This new two-volume book on Spine Surgery is to be recommended for bringing a true 'evidence-based state of the art' on a vast array of spine topics. It feels like reading a succession of well thought about review articles.

Not only is it a multidisciplinary work bringing together respected professionals from all walks of life, but it was written by leading clinicians and scientists from around the globe, giving it a world-class standing. Evidence-based research is fine and necessary, yet, if not placed in the appropriate clinical context, can be ineffectual and sometimes harmful if misapplied.

These volumes should be found on the desk of all those who are involved regularly with matters related to the spine, be it clinically or in research.

Robert Gunzburg MD PhD
Editor-in-Chief
European Spine Journal

Preface

In no other field of medicine does the statement “*There is more than one way to skin a cat*,” apply more than to spinal surgery. Subtle differences in outcome are often seen when comparing direction of surgical approach, choice of surgical implant, and nonoperative versus operative care. Interestingly, variation in treatment has been often geographical. One example is the differences in surgical treatment of cervical myelopathy in Europe, Asia, and North America where surgeons argue for the merits between laminoplasty versus laminectomy and fusion. Our goal was to assemble a worldwide team of authors with the intent of emphasizing the most diverse but evidence supported methodologies for treating spinal pathology. When possible, an author from North America was paired with an author from another continent. The 135-chapter evidence-based text was then edited by the nine spine surgeons representing Brazil, Canada, China, Egypt, Germany, India, Japan, and the United States. Whether someone is a trainee or an expert spine surgeon, our hope is that this international textbook of spinal surgery is a glimpse into how the rest of the world is effectively caring for their patients.

Acknowledgments

We would like to thank Shri Jitendar P Vij (Group Chairman), Mr Ankit Vij (Managing Director), Ms Chetna Malhotra Vohra (Associate Director-Content Strategy), and the production team of Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India, for their cooperation in publishing this book.

Contents

Volume 1

Section 1: General

Magdy Gamal Youssef

1. The Aging Lumbar Spine	3
<i>Isaac L Moss, Howard S An, Stephen P Banco</i>	
2. Anatomy of the Cervical, Thoracic, and Lumbar Spine	17
<i>Ahmed S Mohamed, Alex Ching</i>	
3. Clinical Biomechanics of the Spine	34
<i>Tristan B Fried, Christopher K Kepler, Paul W Millhouse, John Koerner, Henry Dunn, Benjamin Eachus, Priscilla K Cavanaugh, Anita Mikkilineni, Alexander R Vaccaro</i>	
4. Biomechanics of Spinal Fixation	42
<i>Micah Smith, Doug Burton, Darrel S Brodke</i>	
5. Physical and Neurologic Examination of the Spine	57
<i>Charla R Fischer, Ryan T Cassilly, Melvin C Makhni, Mark Weidenbaum</i>	
6. Electrodiagnostic Studies of the Spine	76
<i>Toshihiko Taguchi, Yasuaki Imajo, Mark L Dumonski</i>	
7. Interventional Spinal Diagnostics and Therapeutics	85
<i>Naresh Kumar, Pankaj Kandwal, Wong Hee Kit</i>	
8. Surgical Considerations in the Obese Patient	103
<i>H Michael Mayer</i>	
9. Surgical Considerations in the Geriatric Patient	111
<i>Xuesong Zhang, Yan Wang</i>	
10. Surgery of the Sympathetic System: Thoracoscopic Sympathectomy	121
<i>Sonia Teufack, Joshua E Heller</i>	
11. Stereotactic Radiosurgery of the Spine	125
<i>David M Neils, James McGee, Daniel R Fassett</i>	
12. Intraoperative Neuromonitoring during Spine Surgery	135
<i>Adam T Doan, Maurice L Goins, Richard W Vogel, Anthony K Sestokas</i>	
13. Anesthesia and Perioperative Care of Patients for Spine Surgery	151
<i>Mitch Giffin, Donald Griesdale, Terrence Waters, Kevin Froehlich, Michael Negraeff, Jonathan McEwen, Henrik Huttunen</i>	
14. Spinal Orthoses	167
<i>Christopher Bailey, Parham Rasoulinejad, Abdulaziz Alkuwari, David Hannallah</i>

The Aging Lumbar Spine

Isaac L Moss, Howard S An, Stephen P Banco

Snapshot

» Etiology of Disc Degeneration

INTRODUCTION

The lumbar spine is composed of the five caudal-most fully segmented vertebrae of the spine. Each vertebra is a complex bone composed of several parts (Fig. 1.1). The *vertebral body* serves as the primary weight-bearing structure of the spine. The *lamina* and *pedicles* form the *spinal canal* that contains and protects the neural elements. A central *spinous process* and two lateral *transverse processes* protrude from the vertebrae and serve as attachment points for the paravertebral muscles and ligaments. The *superior* and *inferior articular processes* form synovial joints with the adjacent vertebrae known as the *facet joints*. Multiaxial motion between the vertebrae is achieved through a three-joint complex composed of an anterior intervertebral disc (IVD) separating two vertebral bodies and two posterior facet joints.

The facet joints are lined with articular cartilage and are surrounded by a capsule, typical of synovial joints elsewhere in the body. The IVD, however, has a unique structure consisting of an inner proteoglycan-rich gelatinous nucleus pulposus (NP), surrounded by the annulus fibrosus (AF), an organized fibrous ring with abundant type I collagen content. The entire structure is confined cranially and caudally by cartilaginous end plates.

With age, both the IVD and facet joints can degenerate displaying morphologic changes similar to other articulations in the skeleton, including joint space narrowing,

Fig. 1.1: Mid-sagittal cryotome section of the caudal lumbar spine demonstrating the relationship between the vertebrae, intervertebral discs, and the spinal canal.

subchondral sclerosis, and osteophyte formation (Figs. 1.2A and B).¹ In a segment of the population, this process can lead to a variety of clinical presentations including debilitating back pain, a common condition with enormous psychosocial and economic ramifications. It has been estimated that approximately 85% of individuals in the United States suffer from back pain at some point in their lifetime, with an annual prevalence of 15–45%.² The resulting direct and indirect economic costs have been estimated to be between 14 and 90 billion dollars per year.³ Despite the

Figs. 1.2A and B: Lateral X-ray of a normal lumbar spine (A) and a lumbar spine with advanced degenerative changes (B) including disc space narrowing (arrowheads), osteophyte formation (arrow), and spondylolisthesis (*).

Fig. 1.3: Histologic section of rabbit intervertebral disc demonstrating migration of chondrocytes from the end plate into the nucleus pulposus (arrows). The pyknotic nuclei of notochordal cells undergoing apoptosis are visible in the center of the nucleus.

enormous clinical problem it represents, there is a lack of consensus as to how lumbar degeneration should be defined and which changes, particularly within the IVD, should be considered pathologic or just a normal part of aging.

This chapter will describe the development of the lumbar spine, the morphologic and biochemical features of the normal IVD and vertebrae, as well as the changes that occur with aging and pathologic degeneration. A better understanding of these processes is the first essential step in the development of novel therapies to treat and even potentially reverse the degenerative process and its consequence.

Development of the Spine

The axial skeleton is formed by condensation of mesenchymal cells in somites and their aggregation around the notochord. The segmentation of this perichordal tube results in condensed regions that form the vertebral bodies and noncondensed regions that form the IVDs.^{4,5} The notochordal cells proliferate within the IVD and synthesize an extracellular matrix rich in glycosaminoglycans, forming the original embryonic structure of the NP. The AF, on the other hand, is derived from the surrounding mesenchymal tissue. This gives rise to a distinct border between these two IVD components as well as very different tissue composition and properties.^{6,7} In the NP, the negatively charged aggregating proteoglycans produced by the notochordal cells generate an osmotic gradient that both

attracts and holds waters within the IVD. At birth, the population of notochordal cells within the IVD is estimated to be 2,000 cells/mm³.⁸ Shortly afterward, Fas-mediated mitochondrial caspase-9 activation⁹ results in notochordal cell apoptosis with a resulting cell density of 100 cells/mm³ at 1 year of age and almost none identifiable by late childhood. As the notochordal cell population dwindles, chondrocytic cells migrate from the cartilaginous end plate to repopulate the NP (Fig. 1.3). These cells synthesize both proteoglycan and type II collagen in an effort to maintain extracellular matrix homeostasis.¹⁰ Since these migrated chondrocytes are believed to be the major NP cell type in the adult IVD, NP and articular cartilage biology share many similar features.

The AF, derived from the mesoderm, is composed primarily of type I collagen organized into concentric lamellae synthesized by a fibrocyte-like cell population (Fig. 1.4). The collagen fibrils within the annulus are oriented approximately 30° from the long axis of the spine. Fibrils within each layer are parallel and run in opposing directions to adjacent layers. This organization confers significant tensile strength to AF tissue, which is responsible for resistance to tensile and shearing loads placed on the IVD. Only a small percentage of the dry weight of the AF is made up of proteoglycans. With aging, the distinct border characteristic of the developing NP and AF is lost, resulting in fibrous and highly organized outer AF, and an inner AF with mixed fibrocartilaginous characteristics.

Fig. 1.4: The intervertebral disc composed of a gelatinous nucleus pulposus, surrounded by a fibrous annulus fibrosus. The annulus is composed of concentric lamellae with collagen fibers running in alternating directions, angles approximately 30° from the vertical axis of the spine.

The bony vertebral bodies and cartilaginous end plates are formed by mesenchymal cells above and below the IVD. In early life, blood vessels permeate through these structures providing the disc with nutrients.¹¹

By the third decade of life, the blood vessels that supply the center of the disc have receded. As a result, nutritional support to the IVD comes from diffusion through the end plate and outer AF.¹² The cell density within the IVD decreases to a level lower than almost any other tissue in the body as the disc grows with age and more extracellular matrix (ECM) is laid down.¹³ Much of this sparse cell population is found in the regions closest to the source of nutrition near the periphery of the IVD.

When development is complete, the IVD is a relatively acellular, avascular tissue with little potential for self-repair. As a consequence of this process and the constant biomechanical demands placed on the spine, the balance in production and degradation of extracellular matrix components within the NP and AF becomes disturbed with aging. This can give rise to the morphologic appearance of IVD degeneration, and sometimes, symptomatic discogenic low back pain (LBP).

Biochemistry of the Intervertebral Disc

The biochemical composition of the individual components of the spine dictates the biomechanical behavior

Fig. 1.5: Schematic drawing of the major extracellular matrix component of the nucleus pulposus. Large, predominantly type 2 collagen fibers (pink) are randomly arranged throughout the matrix. Aggrecan molecules (circular inset), composed of highly charged chondroitin sulfate and keratan sulfate monomers connected to a core protein, surround the collagen fibers. Multiple aggrecan molecules are connected to long hyaluronan backbones (green) via link protein to form large proteoglycan aggregates.

of the various structures of the spinal motion segment. Biochemical changes within the IVD are considered the primary drivers of the degenerative process and therefore will be the focus in this section.

The IVD and hyaline cartilage share a similar extracellular matrix molecule profile, likely due to the similar cell type populating both tissues (Fig. 1.5). It is estimated that 60% of the dry weight of the AF and 20% of the dry weight of the NP is made up of various collagen types, making it the most abundant protein in the disc. Both fibrillar (collagen I, II, III, V, XI) and short helical forming (collagen VI, IX, XII) collagen types are present in the disc.¹⁴ Type II collagen is the predominant type within the NP, creating a disordered fibrillar framework for other matrix molecules and cell attachment. There is a shift to a predominance of organized type I collagen with progression from the center of the NP toward the AF. Approximately 80% of the collagen molecules in the outer AF are type I.

The structure and distribution of collagen molecules within the IVD change in at least three significant ways as degeneration progresses.¹ The AF and the NP become more fibrous tissues as a result of an increase in the ratio of type I to type II collagen in both structures. Advanced

glycation end products are formed and accumulate due to the nonenzymatic cross-linking of collagen molecules. Production of collagenases by disc cells is also augmented, leading to enzyme-mediated proteolytic cleavage of collagen fibers. The consequence of these events is a buildup of incompetent fibrous collagen that decreases the compliance of the NP, limits its overall swelling ability, and impairs resistance to compressive loading.¹⁵

Up to 50% of the dry weight of the NP and 20% of the dry weight of the AF is made up of proteoglycans. After collagen, these are the second most abundant group of extracellular matrix molecules within the IVD. Versican, lumican, decorin, biglycan, and fibromodulin are all found in measurable quantities within the IVD; however, aggrecan is by far the most abundant proteoglycan.¹ The NP's ability to attract and bind water is largely due to the highly charged nature of this molecule consisting of chondroitin-6 sulfate and keratan sulfate side chains bound to a core protein. The aggrecan of the IVD also forms large proteoglycan aggregates by binding to hyaluronan through interaction with link protein, further augmenting its ability of attracting water and maintaining disc hydration.

As the disc ages, there is a change in both the amount and character of aggrecan within the IVD. A reduction in both cell numbers and the rate of proteoglycan synthesis per cell leads to a decrease in overall aggrecan production. At birth, chondroitin sulfate is the most abundant glycosaminoglycan side chain present within aggrecan molecules. With age, however, there is a shift to a predominance of keratan sulfate side chains.¹⁶ Water-binding capacity and efficiency is diminished as both aggrecan and aggrecan-hyaluronan aggregates are subject to proteolytic degradation. Additionally, due to the large size of these molecules, the partially digested proteoglycans are not easily scavenged from the disc. Similar to the collagens, these molecules amass within the IVD and are subject to nonenzymatic cross-linking further contributing to the accumulation of advanced glycation end products.¹⁵

The principal proteolytic enzymes produced by native disc cells are a disintegrin and metalloprotease with thrombospondin motifs and matrix metalloproteinases (MMPs).¹⁷ The cells also produce natural antagonists to MMPs, namely, tissue inhibitors of metalloproteinases. These enzymes and enzymatic inhibitors, which are modulated by a number of biochemical stimuli including expression of growth factors and cytokines, are responsible for remodeling and maintenance of IVD matrix homeostasis. Clearly, a certain amount of tissue turnover is required to clear dam-

aged molecules. However, the balance between anabolic and catabolic metabolism within the IVD can be altered due to age-related metabolic changes, genetic predisposition, and biomechanical dysfunction. This balance is generally shifted toward intensified catabolism, thus producing the biochemical changes typical of degeneration.

The consequence of these biochemical changes in collagen and proteoglycan content and enzymatic activity within the disc is a limited ability to adequately dissipate both compressive loads and progressive mechanical incompetence. Additionally, the impaired swelling pressure within the degenerated disc leads to a reduction in exchange of waste and nutrients, further starving the few remaining disc cells, which are diffusion dependent. The progressively fibrous matrix also places increased stress on the mechanically sensitive disc cells. The intracellular response to this microenvironment can lead to increased cell death and/or further upregulation of type I collagen and proteolytic enzyme synthesis, possibly contributing to downward degenerative spiral.¹⁸

Biomechanics

Two adjacent vertebrae, the facets joints, an intervening IVD, and the various connecting ligaments form the functional spinal unit. The AF and end plates enclose the relatively incompressible hydrated NP. Both axial compression and eccentric loading result in even stress distribution across the cartilaginous end plate in nondegenerated IVD.¹⁹ In the unloaded condition, proteoglycans attract and hold water within the NP generating positive intradiscal hydrostatic pressure. When the spine is loaded, stress is transmitted through the compact subchondral bone of the end plate to the NP. This leads to an increase in pressure within the NP that, in turn, is transmitted to the organized lamellar structure of the AF and converted into tensile hoop stress resulting in altered spatial arrangement of the collagen network and a small amount of immediate decrease in disc height. If the load applied to the spine remains constant, slow outflow of fluid through the AF and end plates results in a viscoelastic creep phenomenon with the IVD continuing to lose height over time. When the load is eventually removed, the osmotic pressure generated by the proteoglycans within the healthy NP will cause an influx of fluid from the surrounding tissue to slowly recover the lost height.²⁰ There is, therefore, a regular diurnal variation in IVD height with progressive loss of height during the day when upright, and recovery when supine at night.

Many rehabilitation regimes designed for patients with discogenic back pain are based on the *in vivo* intradiscal pressure measurements in various functional positions reported by Nachemson and Morris.²¹ In their study of undegenerated human discs, the unsupported sitting position resulted in the highest recorded intradiscal pressure (0.8–1.5 MPa). Conversely, the lowest pressures were measured in the discs of relaxed, supine subjects (0.1–0.2 MPa). Lifting, especially with an anterior positioned load, and other strenuous activities resulted in a significant increase in intradiscal pressure. These general trends observed by Nachemson were confirmed in two more recent studies.^{22,23} These studies also found a significant decrease in intradiscal pressure in degenerated IVDs (see Fig. 1.3).

The mechanical properties of the IVD change from those of a viscous semi-fluid to properties closer to those of a solid as the nucleus degenerates and becomes fibrous with decreased proteoglycan and increased collagen content.¹ Stress distribution across the spinal motion segment becomes uneven as the more fibrous NP has a diminished overall swelling capacity and is unable to adequately conform to and transmit applied loads.²⁴ The AF becomes overloaded and structurally damaged, especially when eccentric loads are applied to the IVD. Nucleus pulposus containment eventually fails, often through the development of fissures within the AF, as the degenerative process proceeds. Degenerated IVDs demonstrate altered creep characteristics with larger and more rapid deformation with any given load, and slower recovery when the load is removed.²⁵ As the main load-bearing structure of the functional spinal unit fails, a higher portion of load bearing is transferred to the posterior elements. Osteoarthritic changes similar to other cartilaginous synovial articulations begin to manifest within the overloaded facet joints. While facet joint degeneration does not always progress in parallel to IVD degeneration, facet degeneration is not found in the absence of a degenerated IVD.²⁶

The degenerative cascade proposed by Kirkaldy-Willis and Farfan explains the pathogenesis of spinal motion segment degeneration through three progressive phases.²⁷ In the first “dysfunctional” stage, acute or repetitive injury can lead to the accumulation of microscopic damage within the disc and synovitis within facet joint. In the second “unstable” phase, diminished IVD height, in addition to facet capsule laxity and subluxation, leads to pathologic and potentially painful hypermobility of the degenerated spinal motion segment. Eventually, severe degenerative changes inducing disc osteophyte formation and facet

enlargement lead to the third “stabilization” phase with resolution of the hypermobility present in stage two. The majority of back pain episodes are thought to occur during the first two stages of degeneration. In the third stage, discogenic back pain is relatively uncommon; however, patients may remain or become symptomatic from spinal stenosis due to hypertrophy of the facet joint and disc bulging. Recent cadaveric studies in both the lumbar²⁸ and cervical spine²⁹ have supported this observation, reaffirming the relationship between spinal motion and disc degeneration.

Macroscopic and Radiographic Changes

The biochemical and biomechanical alterations within the IVD result in well-described macroscopic changes. This progressive deterioration is the basis of the grading system proposed by Thompson et al. based on gross pathologic changes visible as the disc degenerates.³⁰

As pathologic examination is not usually practical, clinicians rely on radiographic imaging to diagnose degenerative disc disease. On plain X-ray, disc space narrowing, end plate sclerosis, and osteophyte formation at the margins of the affected level characterize degeneration. In more severe cases, gas collections can be visible within the disc. Degenerative changes on magnetic resonance imaging (MRI) provide a more detailed assessment of the state of the IVD. However, clinical correlation with the radiologic finding is always important, as MRI abnormalities are found in a large percentage of asymptomatic individuals.^{31,32} On T2-weighted sequences, loss of NP hydration results in progressive loss of signal intensity. Pfirrmann et al.³³ described an MRI grading scale of degenerative changes, similar to the pathologic Thompson scale (Table 1.1 and Fig. 1.6). Tears within the AF are often visible,³⁴ as well as end plate signal changes, both of which can be indicative of degenerative disc disease (DDD). Modic et al.³⁵ classified end plate signal changes into two types: Modic type I changes, indicative of augmented marrow fibrovascularity, demonstrate decreased signal intensity on T1-weighted sequences and increased signal intensity on T2-weighted sequences; whereas, Modic type II changes are characterized by increased signal intensity on T1-weighted sequences and isointense or slightly increased signal on T2-weighted sequence. The correlation of these changes with back pain is still the subject of debate.^{36–39}

As degeneration within the disc progresses, arthritic changes in other parts of the spinal motion segment become evident on imaging. Degenerative changes within the facet joint can become clinically important, and severity can be graded with either computed tomography scans

Table 1.1: MRI classification of disc degeneration.

Grade	Structure	Distinction between AF and NP	Signal intensity	IVD height
I	Homogenous, bright white	Clear	Hyperintense, isointense to CSF	Normal
II	Inhomogenous with or without horizontal bands	Clear	Hyperintense, isointense to CSF	Normal
II	Inhomogenous, gray	Unclear	Intermediate	Normal to slightly decreased
IV	Inhomogenous, gray to black	Lost	Intermediate to hypointense	Normal to moderately decreased
V	Inhomogenous, black	Lost	Hypointense	Collapsed disc space

Fig. 1.6: Grading disc degeneration: T2-weighted magnetic resonance images (left panel) and gross pathology mid-sagittal sections (right panel) of intervertebral discs demonstrating progression of degenerative changes from Pfirrmann/Thompson Grade I, with no degeneration to Pfirrmann/Thompson Grade V, with severe degeneration and disc space collapse.

or MRI.^{26,40} The combination of both IVD and facet degeneration can lead to spinal stenosis and segmental instability, known as spondylolisthesis (Fig. 1.7). If degeneration progresses over multiple levels, alteration in both coronal and sagittal alignment can occur resulting in degenerative lumbar scoliosis or kyphosis. When asymmetric degeneration of the IVD and/or the facet joints occurs, the spinal motion segment is loaded unevenly. Over several years, an asymmetric deformity (i.e. scoliosis and/or kyphosis) can develop. The developing deformity further alters the load distribution, setting up a cycle, with the deformity again triggering additional asymmetric degeneration and inducing more asymmetric loading.⁴¹ These changes often occur in postmenopausal females or older men who have altered bone metabolism and some osteopenia.⁴² These patients may experience collapse of weak osteoporotic vertebrae and develop asymmetric bony deformity, which can contribute to further progression of either scoliosis or kyphosis. At each level, translational dislocations in either the coronal plane alone or three-dimensionally can occur in addition to spondylolisthesis, leading to rotational subluxation.⁴³

The degenerative changes not only lead to spinal deformity, but are also likely to result in the development of spinal canal narrowing, known as spinal stenosis. This stenosis, a result of disc narrowing, disc bulging, facet hypertrophy, and vertebral translation, can impinge on the neural elements in the spinal canal or neural foramen. Clinically, patients with stenosis can experience back pain and/or leg pain in the form of radiculopathy or neurogenic claudication.

ETIOLOGY OF DISC DEGENERATION

Lumbar spine degeneration is considered an unavoidable consequence of aging. In one anatomic study, macroscopic

Fig. 1.7: Mid-sagittal (left panel) and axial (right panel) T2-weighted magnetic resonance imaging of the lumbar spine of a 64-year-old woman who presented with both low back and bilateral leg pain. The hallmarks of disc degeneration are apparent at the L4-5 level (arrow head) on the sagittal including loss of nucleus pulposus hydration and disc space narrowing. Facet joint hypertrophic osteophyte formation is evident on the axial images (arrows). These degenerative changes have resulted in spondylolisthesis, with L4 slipped forward on L5 (left panel), and severe spinal stenosis (*, right panel).

disc degeneration was found in 98% of specimens above the age of 70 years, and in only 16% of specimens below the age 20 years.⁴⁴ Fortunately, while extremely common on pathologic examination and imaging, spinal degeneration is frequently asymptomatic.^{31,32} In patients with back pain, it can be a clinical challenge to determine which degenerated structures are the pain generators and which are incidental findings.

There are many etiologic factors that have been linked to the development of spinal degeneration. As discussed previously, the disc cells are responsible for maintenance of homeostasis within the IVD. Therefore, anything that impacts the microenvironment within the NP or alters disc cell metabolism and synthetic rate can accelerate the degenerative process. These factors can be environmental, mechanical, and/or genetic.

Intervertebral disc nutrition has been implicated as a major contributor to degeneration.⁴⁵ As detailed above, the blood vessels supplying the NP recede in the first two decades of life leaving the disc cells largely dependent on diffusion through the end plates and outer AF for nutrition.¹² As the end plates calcify with age, diffusion into

the IVD is impeded further. The cells at the center of the mature NP can be several millimeters from the nearest blood supply, severely limiting nutrient diffusion.¹² Viability of these cells is significantly impacted by the loss of nutritional support, leading to a decreased number of cells over time.⁴⁶ Lack of nutrients and low oxygen tension shift the metabolism of the remaining cells to the anaerobic pathway, leading to lactate production and lowered tissue pH. In these conditions, the rate of matrix synthesis by disc cells drops off further.^{47,48} The combination of a low number of viable cells and less matrix synthesis per cell shifts the balance of homeostasis within the disc to one of net catabolism. Systemic diseases that can alter vertebral blood supply, such as atherosclerosis,⁴⁹ have been associated with higher rates of disc degeneration. Smoking has also been linked to the development disc degeneration and back pain in several epidemiologic studies.^{50,51} The negative effects of smoking on the disc are thought to be mediated both through nutritional restriction^{52,53} and direct nicotine toxicity to disc cells.^{54,55}

Alteration in mechanical loading has also been implicated as a cause of disc degeneration, with changes

in the biomechanical environment leading to biochemical changes within the tissue.^{56,57} Excess, or asymmetric mechanical loading of the disc can lead to localized tissue trauma. Tissue repair will be minimal due to slow turnover of the disc matrix.⁵⁸ Prolonged mechanical loading can lead to a higher rate of apoptosis of IVD cells.⁵⁹ Additionally, excessive hydration or dehydration of the disc has been shown to significantly decrease the rate of matrix synthesis.^{60,61} The combination of repetitive microtraumas and the decreased turnover and synthetic rate of disc cells and matrix, ultimately leads to progressive structural failure of the disc, making it more susceptible to further injury.

Genetic susceptibility has also been implicated as major contributing factor to disc degeneration. The so-called “Twin Spine Study”⁶² compared the rates of IVD degenerative changes in monozygotic twins in three countries with discordant exposure to occupational or sport-related spinal loading. The data demonstrated that genetic factors are the primary predictor of disc degeneration, with heredity accounting for up to 74% of the variance present in the adult population. This dispelled the previously held belief that mechanical injury was the strongest driver of degeneration. Further work by Videman et al.⁶³ demonstrated that polymorphism within vitamin D receptor gene was associated with disc degeneration. Other gene polymorphisms including aggrecan,⁶³ interleukin-1 and COL9A3,^{64,65} COL9A2,⁶⁶ collagen IX and XI,⁶⁷ and MMPs-3⁶⁸ have been linked to the development of disc degeneration.

Chronic low-grade infection has recently received some attention as a potential contributor to disc degeneration and LBP. Albert et al.⁶⁴ cultured herniated disc material from patients undergoing discectomy. The study found microorganisms to be present in 46% of herniations, with the anaerobic bacteria *Propionibacterium acnes* being the most common isolate detected. The study further demonstrated a statistically significant higher rate of type 1 Modic changes in patients with disc material infected with anaerobic bacteria. A follow-up randomized controlled trial demonstrated improved clinical outcomes in patients with chronic back and previous herniated discs after 100 days of antibiotic therapy.⁶⁵ The generalizability of these exciting findings to the general population of LBP patients has yet to be determined.

Pain Generators

An understanding of the biomechanical and biochemical processes as well as the etiologic factors leading to spinal

degeneration is important. However, from a clinical perspective, an essential question remains to be answered—what is the source of pain in the degenerating spinal motion segment? This is especially relevant as there is a poor correlation between the morphologic signs of degeneration and back pain.⁶⁶ No single answer to these questions has emerged; however, it has become clear that several sources of pain exist.

Pain originating from the IVD, termed *discogenic pain*, has long been implicated as a major player in the process; however, its etiology is not well understood. The central end plate and the periannular tissues have the most abundant nerve supply of the IVD.⁶⁷ The outer rim of the AF is thought to contain the bulk of IVD nociceptive fibers arising from the sinuvertebral nerve, a meningeal branch of the spinal nerve originating from the dorsal root ganglia (Figs. 1.8A and B). It has been demonstrated in animal models that the caudal IVDs may be innervated by the L1 or L2 dorsal root ganglia through the sympathetic trunk.⁶⁸⁻⁷¹ Thus, discogenic back pain may be referred to the groin (i.e. the L2 dermatome). There is currently debate in the literature as to whether or not this finding may be of diagnostic or therapeutic value.^{72,73}

Discography, injection of fluid into the IVD, has been used as a provocative test for discogenic pain; however, its accuracy in predicting the source of pain in response to treatment is still quite controversial.⁷⁴ Stretch of an abnormal AF, extravasation of foreign tissue into the peridural space, and pressure on adjacent nervous structures are thought to be mechanism for pain generation. In vitro experiments have demonstrated that human IVD cells increase production of nerve growth factor when exposed to interleukin-1 β and tumor necrosis factor- α , both important proinflammatory cytokines.⁷⁵ This may promote infiltration of nociceptive nerve fibers into the disc and lead to back pain. Other authors have attempted to find differences in morphologically degenerate discs with varying degrees of clinical symptoms. Keshari et al. found that proteoglycan, lactic acid, and collagen ratio as measured by nuclear magnetic resonance spectroscopy differed in symptomatic and nonsymptomatic abnormal IVDs.⁶⁶ These findings may serve as the basis for a diagnostic test at some point in the future.

The facet joints have been noted to be a major source of pain since early in the 20th century.^{76,77} The load to the facets is maximal with lumbar hyperextension, and is further increased when disc height is lost as a result of degeneration.⁷⁸ Experiments using both provocative and

Figs. 1.8A and B: Innervation of the intervertebral disc. (A) Ascending and descending branch of the sinuvertebral nerve shown arising from the dorsal root ganglion (DRG). (B) Course of the recurrent sinuvertebral nerve from the DRG through the vertebral foramen innervating the outer annulus fibrosus.

Source: Raj PP. Intervertebral disc: anatomy-physiology-pathophysiology-treatment. *Pain Pract.* 2008;8(1):18-44.

therapeutic intra-articular injections confirmed the facet joints to be a significant pain generator in patients with LBP.^{79,80} Additionally, both sensory and autonomic nerve fibers as well as neurotransmitters have been shown to be present in the facet capsule.⁸¹ The lumbar facet joints are segmentally innervated by the medial branch of the dorsal rami.⁸² Thus, intra-articular facet joint injections, and medial branch block or ablation is a commonly employed treatment for chronic LBP. Evidence for the efficacy of these treatments remains unclear, especially in the long term.⁸³⁻⁸⁵

Nerve root compression or irritation can also be a mechanism for pain production in lumbar degeneration. While this most often presents as radiculopathy, with pain radiation to the dermatomes of the lower extremities, nerve compression can also cause isolated back pain. The pathophysiologic basis for neurogenic pain is a subject of debate; however, recent studies have demonstrated increased neuropathy, ectopic discharge, and mechano-sensitization of nerve roots when exposed to NP tissue, a situation commonly found in the degenerated lumbar spine.⁸⁶

As more information emerges in the literature, it is clear that the area of pain generation deserves further study

both mechanistically and diagnostically in order to enable researchers and clinicians to develop and plan appropriate therapies.

Biologic Therapy for Lumbar Degeneration

Although our understanding of the mechanisms of spinal degeneration has advanced significantly, the current standard of care for patients with lumbar degeneration is aimed at symptomatic control rather than reversal of the disease process. Nonsurgical therapeutic modalities including patient education, medications, exercise therapy, and occasionally various types of injections are commonly employed. In a small number of patients with unrelenting symptoms, surgical intervention to decompress, stabilize, or even replace the affected motion segments is recommended. While these interventions can be effective, they come at a high cost and put patients at risk of complications. As discussed previously, spinal degeneration is believed to begin with changes in the NP of the IVD. Thus, biologic repair to slow or reverse the early nucleus degenerative process is an attractive alternative to the current

end-stage mechanical treatment approaches. Successful biologic repair strategies require a consideration of one or all of the following components: delivery of cells, the application of therapeutic molecules, and the supplementation of matrix.¹¹

The density of cells present in the NP decreases significantly with aging and degeneration.¹³ In order for tissue repair to be possible, a new population of cells is necessary to produce appropriate extracellular matrix molecules and supplement the existing population. This can be achieved by implantation of new healthy cells into the disc, and/or by stimulation of native cell proliferation with bioactive molecules. A small clinical study examined the utility of autologous disc cell harvest, followed by *ex vivo* expansion and subsequent reimplantation.⁸⁷ While the possibility of supplementation with autologous cells is attractive, concerns with the practical application of this strategy and the infrastructure necessary to harvest and expand the cells *ex-vivo* have prompted the investigation of other source of cells. Pluripotent cells, such as mesenchymal stem cells, are interesting candidates for cell supplementation as they can be harvested from several sources and are highly metabolically active in the proper environment. They have thus become the focus of many studies. Experiments conducted both *in vitro* and *in vivo* have demonstrated that mesenchymal stem cells can be successfully differentiated into chondrocyte-like cell populations. Under appropriate conditions, these cells can express IVD matrix proteins and cell surface markers.⁸⁸⁻⁹⁹ Based on successful recent *in vivo* work with an ovine model of disc degeneration,¹⁰⁰ a phase 2 human clinical trial using cell-based therapy is currently underway. The study is designed to determine the safety and initial efficacy of injecting mesenchymal precursor cells in a hyaluronic acid carrier into the degenerating IVDs. Results of this study have yet to be released; however, this represents an important step in the translation of this technology from the laboratory to clinical application.

The delivery of bioactive molecules to alter the catabolic environment of the degenerating NP is another cornerstone of a successful regenerative strategy. There are four basic categories of potentially therapeutic bioactive molecules: anticatabolics, mitogens, chondrogenic morphogens, and intracellular regulators.¹¹ The chondrogenic morphogens, which include transforming growth factor- β and the bone morphogenetic protein (BMP) family, have been the focus of much investigation in this field. Proteoglycan and collagen synthesis is increased in response to transforming growth factor- β treatment of both healthy

and degenerated IVD cells *in vitro*.¹⁰¹⁻¹⁰³ The BMP family of growth factors is currently used clinically to promote fracture healing and spinal fusion as they have been shown to induce osteogenesis. Interestingly, disc cells treated with BMP-2 and BMP-7 (osteogenic protein-1) show increased production of collagen type II and proteoglycans, without osteogenic effects seen in other environments.¹⁰⁴⁻¹⁰⁷ In preclinical animal experiments, direct injection of a single dose of BMP-7 into degenerating discs resulted in improved disc height, restoration of viscoelastic biomechanical properties, and healthier functional metabolism.^{108,109} Another member of the BMP family, growth differentiation factor-5, was found to improve IVD cell viability and extracellular matrix production *in vitro*, and to curb progression of degeneration in a preclinical model.¹¹⁰ Several other potentially therapeutic molecules, including interleukin-1 receptor antagonist, platelet-derived growth factor, and insulin growth factor-1, are currently being investigated for their effects on IVD cells and disc degeneration.

Despite encouraging *in vitro* and *in vivo* studies, there is some concern that a single direct injection of a therapeutic molecule into the IVD may not be sufficient to stimulate and maintain the repair process. Gene therapy has been proposed as a method to achieve long-term sustained expression of stimulatory molecules from cells within the IVD. The potential for immune reaction and the spread of disease have raised safety concerns with the employment of viral vectors to deliver gene therapy elsewhere in the body. Due to its relative avascularity, cells of the immune system have limited access to the IVD and it is considered to be an immune-privileged environment. Thus, viral transfection of both native disc cells and exogenous chondrocytes with vectors to promote expression of several therapeutic factors has been attempted. The genes of interest include both intracellular regulatory proteins and growth factors. Both cell culture work and *in vivo* experiments examining the delivery of the transcription factor Sox-9, known to be an important regulator of the chondrocytic phenotype, to nucleus cells via a recombinant adenovirus have demonstrated upregulation of proteoglycan synthesis and reversal of early degeneration.^{111,112} Increased cell viability and augmented production of extracellular matrix molecules have also been demonstrated with adenoviral transfection of both animal and human NP cells with several growth factors including transforming growth factor- β 1, BMP-2, BMP-7, and insulin growth factor-1.¹¹²⁻¹¹⁴ Data from these experiments have served as a proof of principle that transfections of cells with stimulatory genes and subsequent implantation of

these altered cells into the degenerating disc may represent an effective strategy for cell therapy and the delivery of therapeutic molecules in a single treatment.

Scaffolds to serve as cell or drug carriers and supplement the degenerating extracellular matrix are the final component of a successful IVD tissue-engineering strategy. A wide variety of candidate materials have been investigated. A scaffold must provide a favorable microenvironment for cell growth, migration, and synthesis of extracellular matrix in order to be successful. Ideally, constructs must have mechanical properties capable of withstanding the loads within the IVD in the short term, and then incorporate and remodel as the disc regenerates.¹¹⁵ Many of the scaffolds studied are designed by combining fibrillar molecules and glycosaminoglycans in an attempt to re-create the normal matrix components of the IVD.¹¹⁶⁻¹²⁰ This aspect of regenerative therapies continues to be the subject of active investigation.

SUMMARY

The lumbar spine is a complex structure elegantly designed to support upright posture and protect the neural elements. Lumbar degeneration occurs as an inevitable part of aging and results in altered biochemical and biomechanical function as well as anatomic abnormalities. These changes result in a wide spectrum of symptoms, from completely asymptomatic to debilitating pain and functional decline. As our understanding of the makeup and function of the various components of the lumbar spine advances, opportunities for interventions to halt or reverse this process at early stages are evolving. In the future, these interventions may allow the next generation of physicians to change, for the better, the way we treat the aging lumbar spine.

INTRODUCTION

The vertebral column is composed of alternating vertebrae and intervertebral (IV) discs supported by spinal ligaments and muscles. All of these elements, bony, cartilaginous, ligamentous, and muscular, are essential to the structural integrity of the spine. The spine serves three vital functions: protecting the spinal cord and nerves, transmitting the weight of the body, and providing a flexible axis for movements of the head and the torso. The vertebral column is capable of extension, flexion, lateral bending, and rotation. However, the degree to which the spine is capable of these movements varies according to region.

The spine is a segmental column of similar formed bones that constitutes the major part of the axial skeleton. Its individual elements are united by a series of IV articulations to form a flexible, although neuroprotective, support to the trunk and limbs.¹

The inclusion of all articular tissues, the overlying spinal muscles, and the segmental contents of the vertebral canal and IV foramen into a single functional and anatomic unit was first suggested by Junghanns.² Originally called the “motor” segment, this unit represents a useful concept that stresses the developmental and topographic interdependence between the fibrous structures that surround the IV foramen and the functioning of the structures that pass through it.

DEVELOPMENT

Overview

Much of the understanding of human embryology has been elucidated from extensive experimental manipulations of organisms such as *Drosophila melanogaster*, chicken, and mice.^{3,5,6} Human embryology, from conception through the embryonic and fetal periods and, finally, birth, has been characterized in detail. The development of musculoskeletal structures associated with the trunk of the human body is a multistep process involving differential gene expression as well as cell interactions and cell signaling between precursor tissues. This process occurs during the 4th through 8th weeks of development, with a mass of ectodermal cells dividing and forming a tube that migrates cranially in the midline between the ectoderm and endoderm. The notochord arises from cells in the primitive streak. It develops from cranial to caudal by adding cells. The notochord itself induces formation of the neural groove that closes by the end of the 4th week, forming the neural tube. Failure of this step is believed to be the cause of myelomeningocele.³⁷

Bony Development

The precursors to the vertebrae are the somites that form the paraxial mesoderm. The positional information of the

Figs. 2.1A and B: Schematic of somite differentiation. (A) Newly formed somites consist of an epithelium and a mesenchymal somitocoele. (B) Sclerotomal cells migrate medially around the notochord and will eventually become the vertebrae.

somite is imparted early in gestation and a displaced somite will continue to have the morphology of the intended location.⁶ All 30 pairs of somites are present at 4.5 weeks of gestation. The sclerotomal cells from the paired somites migrate medially around the notochord. They separate it from the dorsal neural tube and ventral primitive gut. The neural arches develop from the ventral to dorsal and enclose the neural tube. The spinal nerves and dorsal root ganglia arise at the level of the somite and enter the myotome at the beginning of the 6th week of gestation. Neural crest cells then accumulate just before the cranial closure of the neural tube and are situated between the neural tube and the somites. These cells are the precursors to the peripheral nervous system (Figs. 2.1A and B).

The formation of the vertebrae is dependent on the highly coordinated migration of sclerotomal cells both toward the midline and along the rostral/caudal axis.^{7,8} Soon after epithelial-mesenchymal transformation, cells from the ventral/medial sclerotome migrate toward the notochord, where they will contribute to the vertebral body and IV discs. This is followed by the migration of the lateral sclerotomal cells dorsally to form the vertebral pedicles and the laminae of the neural arches. Resegmentation of the sclerotome is intimately linked to the specification of the rostral and caudal domains early in somitogenesis. Disruption of rostral/caudal polarity after somite formation has also been shown to impact resegmentation, though to a lesser extent.⁴ In paraxis-deficient embryos, ventral cartilage fails to segment into vertebral body and IV discs, while the lateral neural arches are unaffected. For example, disruption of the caudal identity of somites through inactivation of the Notch pathway leads to fused vertebral bodies and an absence of neural arches.

At birth, only 30% of the spine is ossified. The spine has a well-established pattern of growth throughout the infantile, juvenile, and adolescent period, during which time

the spine will nearly triple in length. The rate of growth accelerates from birth to 2 years of age; it becomes steadier from age of 2 to 10 and then starts to accelerate again during the prepubescent period.

Intervertebral Disc Development

The genesis of the IV disc is intimately linked to somite polarity and sclerotome resegmentation and as such is dependent on the Notch/Mesp2 signaling. The annuli fibrosi of the IV discs forms from condensed mesenchyme derived from the somitocoele at the border of the rostral and caudal domains during resegmentation.

Development of the annuli fibrosi and its maintenance in adults is dependent on members of the transforming growth factor beta (TGF- β) superfamily.^{9,10} Inactivation of TGF- β type II receptor (Tgfr2) in type II collagen-expressing cells results in an expansion of Pax1/Pax9 expression and the loss of IV discs. GDF-5 and BMP-2 promote cell aggregation and expression of the chondrogenic genes instead of osteogenic genes in the IV discs.

Musculature Development

The dorsolateral subpopulation of somatic cells is called the dermomyotome. These cells maintain their segmental arrangement and give rise to a new layer of cells, the myotome, which provides the skeletal musculature for its own segment. The “rearrangement” or organization of sclerotomes into definitive vertebrae causes the myotomes to overbridge the IV discs, allowing for movement of the spine. The remaining subset of cells, after migration of the myoblasts from the myotomes, is referred to as the dermatome, and forms the dermis on the dorsal side of the embryo.

A segmental nerve associates with the dermatome and the myotome. This early contact of the nerve and differentiating muscle not only provides motor innervation, but

also provides sensory innervation, which develops to recognize pressure, touch, and temperature from the skin surfaces. This area of skin is supplied by branches of a specific single spinal nerve and, eventually, contributes to the dermis of the skin and is known as a dermatome. Although growth causes some changes in the original segmental size, these distinct dermatome patterns are maintained throughout life. The dermis on the ventrolateral side of the embryo is derived from the somatic mesoderm.^{3,5}

MUSCULOSKELETAL ANATOMY

Bony and Joint Anatomy

The vertebral column is flexible and formed of series of bones called vertebrae. The average spine consists of 33 vertebrae, seven cervical, 12 thoracic, and five lumbar plus five sacral and four coccygeal.

The vertebrae in the *cervical region* are much smaller than those found in other parts of the human spine.

Morphologically, the top two vertebrae of the spine are highly unique and form a set of articulations that provide a disproportionate amount of overall cervical mobility through these segments. The atlas serves as a ring or washer that the skull rests upon and articulates in a pivot joint with the dens or odontoid process of the axis (Fig. 2.2). Approximately 50% of flexion and extension of the neck happens between the occiput and C1; similarly, 50% of the rotation of the neck happens between C1 and C2.¹¹⁻¹³ There is no articular disc between these upper two levels of the spine.

Fig. 2.2: Unique C1-C2 anatomical relationship.

The atlas (C1) is ring shaped and does not have a body, unlike the rest of the vertebrae. Fused remnants of the atlas body have become part of C2 (the axis), where they are called the odontoid process, or dens. The odontoid process is held in tight proximity to the posterior aspect of the anterior arch of the atlas by the transverse ligament, which stabilizes the atlantoaxial joint. On each C1, lateral mass is a superior and inferior facet joint. The superior articular facets are kidney shaped, concave, and face upward and inward. These superior facets articulate with the occipital condyles, which face downward and outward. The relatively flat inferior articular facets face downward and inward to articulate with the superior facets of the axis. The joints are inclined at an angle of 45° from the horizontal plane and 85° from the sagittal plane. This alignment helps prevent excessive anterior translation and is important in weight bearing.

The craniocervical junction and the atlantoaxial joints are secured by the external and internal ligaments. The external ligaments consist of the atlanto-occipital, anterior atlanto-occipital, and anterior longitudinal ligaments. The internal ligaments, by allowing spinal column rotation, provide further stabilization and prevent posterior displacement of the dens in relation to the atlas and consist of the following (Figs. 2.3A to C):

- The transverse ligament holds the odontoid process in place against the posterior atlas, which prevents anterior subluxation of C1 on C2.
- The accessory ligaments arise posterior to and in conjunction with the transverse ligament and insert into the lateral aspect of the atlantoaxial joint.
- The apical ligament lies anterior to the lip of the foramen magnum and inserts into the apex of the odontoid process.
- The paired alar ligaments secure the apex of the odontoid to the anterior foramen magnum.
- The tectorial membrane is a continuation of the posterior longitudinal ligament to the anterior margin of the foramen magnum.
- The 3 cm × 5 mm accessory atlantoaxial ligament not only connects the atlas to the axis, but also continues cephalad to the occipital bone; functionally, it becomes maximally taut with 5–8° of head rotation, lax with cervical extension, and maximally taut with 5–10° of cervical flexion; it seems to participate in craniocervical stability.^{14,15}

In the subaxial cervical spine, the minimal weight-bearing status of the cervical vertebrae allows the bones to have small bodies. The mobility of the cervical spine is

Figs. 2.3A to C: Ligamentous structure of the upper cervical spine. (A) Sagittal view; (B) Posteroanterior (PA) view, (C) Anteroposterior (AP) view.

permitted by the articular processes, which lie at approximately 45° from the horizontal plane. Most cervical vertebrae have bifid (split) spinous processes that serve as attachments to the muscles of the neck. The transverse processes of the cervical vertebrae have a transverse foramen laterally; from C6 and above, this serves as the passageway for the vertebral artery on its way into the cranium. Articulations include disc-vertebral body articulations, uncovertebral joints, and zygapophyseal (facet) joints.

The *thoracic spine* includes 12 vertebrae that appear to have slightly larger bodies than those of the cervical region. The size of the vertebral bodies increases in proportion to the amount of weight borne by the bone. The vertebral body becomes larger as one moves lower in the spinal column. The thoracic vertebrae have characteristically long spinous processes and these processes are generally angled downward throughout the 12 vertebrae. There are specialized facet joints where the ribs articulate with the vertebral

body and/or the transverse processes. The orientation of the articular facets in the thoracic level is at an approximate 60° angle from the horizontal plane. Each thoracic vertebra articulates with both the vertebra above and the vertebra below as well as with the IV disc between the adjacent vertebral bodies. The head of the rib articulates with a vertebral body in one location (vertebra 10–12) on each side of the bone or in two locations (vertebra 1–9). Most ribs (vertebra 1–9) also articulate with the transverse process.

The *lumbar spine* consists of five vertebrae, each larger than one above it. The spinous processes in the lumbar spine are characteristically short and thick. The articular processes generally lie in the sagittal plane, with variations being common.¹⁵⁻¹⁷ This is especially in the transitional vertebrae: the first lumbar having characteristics of the thoracic as well as the lumbar facets, and the last lumbar transitioning into the sacral facet alignment.

The body of a typical lumbar vertebra articulates with the level both above and below through the IV disc and facet joints. The fifth lumbar vertebra articulates with the sacrum at the interarticular, and in some cases the transverse process of one or both sides will be elongated and articulated with the sacrum (sacralization of the lumbar vertebra).

The *sacrum* consists of five fused vertebrae, giving the appearance of one solid bone. The vertebral canal continues through the sacrum, with the IV foramina aligning either anteriorly or posteriorly. The sacrum provides the connection between the lower extremities, pelvic ring, and the spine. The first sacral vertebra articulates with the inferior articular facets of L5. Laterally, the sacrum articulates with the ilium at the right and left sacroiliac joints.

Inferiorly, the sacrum articulates with the most superior coccyx bone. Three or four small bones comprise the *coccyx*. These small bones have no vertebral foramen and thus are not like other bones of the spine.

The *IV disc* serves multiple functions: as a primary stabilizer of the vertebral bodies, as a shock absorber, and a hydraulic jack. Around its circumference, a lamina of fibrous tissue and fibrocartilage forms the annulus fibrosus; and, at its center, a soft, pulpy, highly elastic substance, of a yellowish color, projects considerably above the surrounding level when the disc is divided horizontally. This pulpy substance (the nucleus pulposus), especially well developed in the lumbar region, is the remnant of the notochord. The laminae are arranged concentrically; the outermost

Fig. 2.4: Intervertebral disc.

consist of ordinary fibrous tissue, the others of white fibrocartilage. The laminae are not quite vertical in their direction, those near the circumference being curved outward and closely approximated, while those nearest the center curve in the opposite direction and are somewhat more widely separated. The fibers of each lamina are directed, for the most part, obliquely from above downward, the fibers of adjacent laminae passing in opposite directions and varying in every layer, so that the fibers of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each fibrocartilage. The pulpy substance has no such arrangement, and consists of a fine fibrous matrix, containing angular cells united to form a reticular structure (Fig. 2.4).¹⁵

Bony Surfaces

Anterior surface: When viewed from front, the width of the bodies of the vertebrae is seen to increase from the second cervical to the first thoracic; there is then a slight diminution in the next three vertebrae; below this there is again a gradual and progressive increase in width as low as the sacrovertebral angle. From this point, there is a rapid diminution to the apex of the coccyx.¹⁹

Posterior surface: The posterior surface of the vertebral column presents in the median line the spinous processes. In the cervical region (with the exception of the second and seventh vertebrae), these are short and horizontal plane,

with bifid extremities. In the upper part of the thoracic region, they are directed obliquely downward; in the middle they are almost vertical; and in the lower part they are nearly horizontal. In the lumbar region, they are nearly horizontal. The spinous processes are separated by considerable intervals in the lumbar region, by narrower intervals in the neck, and are closely approximated in the middle of the thoracic region. Occasionally, one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the vertebral column.¹⁹ On either side of the spinous processes is the vertebral groove formed by the laminae in the cervical and lumbar regions, where it is shallow, and by the laminae and transverse processes in the thoracic region, where it is deep and broad; these grooves lodge the deep muscles of the back. Lateral to the vertebral grooves are the articular processes, and still more laterally the transverse processes. In the thoracic region, the transverse processes stand backward, on a plane considerably behind that of the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, lateral to the pedicles and between the IV foramina. In the thoracic region they are posterior to the pedicles, IV foramina, and articular processes. In the lumbar region, they are in front of the articular processes, but behind the IV foramina (Figs. 2.5A to D).

Lateral surfaces: The lateral surfaces are separated from the posterior surface by the articular processes in the cervical and lumbar regions, and by the transverse processes in the thoracic region. They present, in front, the sides of the bodies of the vertebrae, marked in the thoracic region by the facets for articulation with the heads of the ribs. More posteriorly are the IV foramina, formed by the juxtaposition of the vertebral notches, oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar.¹⁹ They transmit the spinal nerves and are situated between the transverse processes in the cervical region, and in front of them in the thoracic and lumbar regions.

Anatomy of Muscles and Ligaments

The lumbar vertebral column is supported by many large muscle groups and spinal ligaments that act to stabilize movement and maintain upright posture.^{18,19} The muscles belong to three groups, intertransverse, anterolateral, and posterior, each with many individual muscles with varying

functions. Additionally, abdominal muscles function to flex the spine, increase intra-abdominal pressure, and support the internal organs. The spinal ligaments function to prevent excessive flexion of the lumbar spine, and for this purpose are primarily arranged posterior to the center of sagittal plane rotation.¹⁸ Other muscles like the trapezius and latissimus dorsi in the back are associated with movement of the neck and shoulder.

The integrity of back muscles provides support for the head and trunk of the body, strength in the trunk of the body as well as a great deal of flexibility and movement. The upper back has the most structural support with the ribs firmly attached to the thoracic spine; the lower back has the greatest flexibility allowing both flexion and extension.

The longus colli muscle is situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is broad in the middle, narrow and pointed at either end, and consists of three portions, a superior oblique, an inferior oblique, and a vertical. The superior oblique portion arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae and, ascending obliquely with a medial inclination, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas.¹⁹ The inferior oblique portion, the smallest part of the muscle, arises from the front of the bodies of the first two or three thoracic vertebrae, and, ascending obliquely in a lateral direction, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The vertical portion arises, below, from the front of the bodies of the upper three thoracic and lower three cervical vertebrae, and is inserted into the front of the bodies of the second, third, and fourth cervical vertebrae (Figs. 2.6A and B).¹⁹

The psoas major is a long fusiform muscle located on the side of the lumbar region of the vertebral column and brim of the lesser pelvis. It joins the iliacus muscle to form the iliopsoas. In <50% of human subjects, the psoas major is accompanied by the psoas minor. On the lumbar spine, unilateral contraction bends the trunk laterally, while bilateral contraction raises the trunk from its supine position. It forms part of a group of muscles called the hip flexors, whose action is primarily to lift the upper leg toward the body when the body is fixed or to pull the body toward the leg when the leg is fixed. Due to the frontal attachment on the vertebrae, rotation of the spine will stretch the psoas. Tightness of the psoas can result in lower back pain by compressing the lumbar discs.

Figs. 2.5A to D: Surface anatomy of the vertebrae.

Figs. 2.6A and B: Ligamentous structures of cervical (A) and thoracic (B) spines.

Fig. 2.7: Ligamentous structures of lumbar spine.

The IV discs and facet joints provide the spine with stability as they tie the 24 vertebrae together into a coherent whole, at the same time bestowing mobility and permitting each vertebra to move on its neighbors.

The spinal ligaments work in much the same manner. They not only play a crucial role in preventing the spine from collapsing, but they also allow movement within a predetermined range, winding up like springs in the process, and storing elastic energy that can then be used to return the spine to its previous posture.

The spinal ligaments all come together to form a continuous, dense connective tissue around the spine—a stocking that then reaches out to the entire body, connecting the vertebral column and its contents with the torso, head, limbs, and sacrum.

The spinal ligaments consist of:

- The anterior longitudinal ligament that runs from the base of the skull along the front of each vertebral body and disc and down the anterior sacrum. It fuses with the periosteum that wraps tightly around each vertebra. This ligament is the only spinal ligament that resists backward bending and limits the forward curve of the neck and lumbar regions.
- The posterior longitudinal ligament that also melds with the periosteum of the vertebral bodies and skull, but this time posteriorly. It runs along the dorsal aspect of the vertebral bodies and discs and down into the canal that lies within the sacrum. It offers attachment

sites for the dural sac of the spinal canal. It tightens with forward bending.

- The facet joint capsule, a balloon-like structure that wraps around each facet joint. Its sensory receptors likely guide the movement between adjacent vertebrae.
- The ligamentum flavum that connects the back of the vertebral arches and forms the back wall of the spinal canal. It is known as the yellow ligament because of the color imparted by the preponderance of elastic fibers. Off to the sides, it fuses with the facet joint capsules. In the midline, it turns posteriorly to become the interspinous ligament. Lengthened by flexion of the spine, its elastic fibers supply a strong returning force. The area of the spine with the most flexion, the lumbar region, is where the ligamentum flavum is the thickest.
- The interspinous ligament running between the spinous processes. Its more anterior fibers are rich in elastin and blend with the ligamentum flavum; the more posterior fibers meld with the supraspinous ligament. The interspinous ligament and (especially) the ligamentum flavum control for excessive flexion and anterior translation.²⁰⁻²²
- The intertransverse ligaments that bind the ends of the transverse processes and resist side bending to the opposite side.
- The supraspinous ligament that connects the tips of the spinous processes and goes on to meld with the thoracolumbar fascia as well (Fig. 2.7).

ANATOMY OF NEUROLOGIC STRUCTURE

The nervous system is the most complicated and highly organized of the various systems that make up the human body. It is the mechanism concerned with the correlation and integration of various bodily processes and the reactions and adjustments of the organism to its environment. In addition, the cerebral cortex is concerned with conscious life. It may be divided into two parts, central and peripheral.¹⁹

The central nervous system consists of the encephalon or brain contained within the cranium, and the spinal cord lodged in the vertebral canal; the two portions are continuous with one another at the level of the upper border of the atlas vertebra.

The peripheral nervous system consists of a series of nerves by which the central nervous system is connected with the various tissues of the body. For descriptive purposes, these nerves may be arranged in two groups, cerebrospinal and sympathetic. This arrangement, however, is an arbitrary one, since the two groups are intimately connected and closely intermingled. Both the cerebrospinal and sympathetic nerves have nuclei of origin (the somatic efferent and sympathetic efferent) as well as nuclei of termination (somatic afferent and sympathetic afferent) in the central nervous system.

The medulla spinalis, or spinal cord, forms the elongated, nearly cylindrical, part of the central nervous system that occupies the upper two-thirds of the vertebral canal. Its average length in the male is about 45 cm, in the female about 42–43 cm, while its weight amounts to about 30 g. It normally extends from the level of the upper border of the atlas to either the lower border of the first or upper border of the second lumbar vertebra. Above, it is continuous with the brain; below, it ends in a conical extremity, the *conus medullaris*. A delicate filament, the *filum terminale*, descends from the apex of the *conus* as far as the first segment of the coccyx.

Thirty-one pairs of spinal nerves spring from the medulla spinalis, each nerve having an anterior, or ventral, root and a posterior, or dorsal, root. The dorsal root has an oval swelling, the spinal ganglion, which contains numerous nerve cells. Each root consists of several bundles of nerve fibers, and at its attachment extends for some distance along the side of the spinal cord. The pairs of spinal nerves are grouped as follows: eight cervical, 12 thoracic, five lumbar, five sacral, one coccygeal. For convenience of

description, the medulla spinalis is divided into cervical, thoracic, lumbar, and sacral regions, corresponding with the attachments of the different groups of nerves. Although no transverse segmentation is visible on the surface of the spinal cord, it is convenient to regard it as being constructed of a series of superimposed spinal segments or *neuromeres*, each of which has a length equivalent to the extent of attachment of a pair of spinal nerves. Since the extent of attachment of the successive pairs of nerves varies in different parts, it follows that the spinal segments are of varying lengths; thus, in the cervical region they average about 13 mm, in the mid-thoracic region about 26 mm, while in the lumbar and sacral regions they diminish rapidly from about 15 mm at the level of the first pair of lumbar nerves to about 4 mm opposite the attachments of the lower sacral nerves.

The typical spinal nerve is formed by the combination of nerve fibers from the dorsal and ventral roots of the spinal cord. The dorsal roots carry afferent sensory axons, while the ventral roots carry efferent motor axons. The spinal nerve emerges from the spinal column through IV foramen. This orientation is true for all spinal nerves except for the first spinal nerve pair, which emerges between the occipital bone and the atlas. As a result, the cervical nerves are numbered by the vertebra below, except C8, which exists below C7 and above T1. The thoracic, lumbar, and sacral nerves are then numbered by the vertebra above. In the case of a lumbarized S1 vertebra (L6) or a sacralized L5 vertebra, the nerves are typically still counted to L5 and the next nerve is S1 (Figs. 2.8 and 2.9).

Outside the vertebral column, the nerve divides into branches. The dorsal ramus contains nerves that serve the dorsal portions of the trunk carrying visceral motor, somatic motor, and somatic sensory information to and from the skin and muscles of the back. The ventral ramus contains nerves that serve the remaining ventral parts of the trunk and limbs and carrying visceral motor, somatic motor, and sensory information to and from the ventrolateral body surface, structures in the body wall, and the limbs.

The anterior divisions of the lumbar, sacral, and coccygeal nerves form the lumbosacral plexus, the first lumbar nerve being frequently joined by a branch from the 12th thoracic. For descriptive purposes, this plexus is usually divided into three parts—the *lumbar*, *sacral*, and *pudendal plexuses*.^{19–24} The nerves pass obliquely outward behind the *psoas major*, or between its fasciculi, distributing filaments to it and the *quadratus lumborum*. The first three

Figs. 2.8A and B: Anatomy of the spinal cord and nerves.

Figs. 2.9A and B: (A) Lumbar spine anatomy: sagittal view. (B) Lumbar plexus.

and the greater part of the fourth are connected together in this situation by anastomotic loops, and form the *lumbar plexus*. The smaller part of the fourth joins with the fifth to form the *lumbosacral trunk*, which assists in the formation of the sacral plexus. The fourth nerve is named the *nervus furcalis*, from the fact that it is subdivided between the two plexuses (see Fig. 2.9B).

VASCULAR ANATOMY OF THE SPINE

The basic arrangement of the spinal system consists of a grid of transversely oriented segmental vessels, connected by various longitudinal channels. This simple bit of knowledge goes a long way in understanding spinal vascular anatomy.

Each vertebral body, its ribs, muscle, nerves, and dermatome, correspond to one level or segment. It is perhaps easiest to appreciate this concept at the thoracic level, where each rib, vertebral body, and other elements constitute the prototypical segment. In the early human embryo, the neural tube is initially supplied by simple diffusion. When the limits of this nutrition are reached (at about 200 μm), a primitive vascular system consisting of paired dorsal and ventral aortae (longitudinal vessels) and transversely oriented segmental arteries come into play to vascularize the developing tissue of the embryo.

As the tissue of spinal cord continues to enlarge, new longitudinal connections form between the transverse segmental arteries, most likely to facilitate distribution of blood within the vascular system. This pattern is seen throughout the body, but is somewhat easier to recognize in the vertebrospinal arterial system, where it gives rise to adult anterior spinal artery and numerous extradural longitudinal segmental connections.²⁵ The same pattern of development takes place in the extra-axial, paravertebral space, where longitudinal connections between segmental arteries form a multitude of adult vessels, such as the vertebral, prevertebral, pretransverse, deep cervical, lateral spinal, and other arteries.

The basic arterial *vertebrospinal* vascular unit consists of two segmental vessels, left and right, arising from the dorsal surface of the aorta. The vessel curves posterolaterally in front of the vertebral body, and sends small branches into its marrow. In front of the transverse process, the segmental artery bifurcates into a dorsal branch and an intercostal branch. The intercostal segment provides blood supply to the rib and adjacent muscle and other tissues. The dorsal branch feeds the posterior elements

and, via the neural foramen, sends branches to supply the local epidural and dural elements, as well as a radicular artery to nourish the nerve root.

At some levels, the radicular artery is enlarged because it maintains its embryonic access to the anterior spinal artery. At this level, the artery is called “radiculomedullary” because it also supplies a large segment of the spinal cord.

The system varies in the cervical, upper thoracic, and sacral segments (i.e. exceptions are greater than the rule), but the basic principle of segmental dural and radicular vessels supplying neural tube elements is a very useful guide. Variation comes most often in the form of segmental vessel origin. The descending aorta provides blood supply for most thoracic and lumbar segments; the vertebral artery, the subclavian branches (costocervical trunk, for example), supreme intercostal artery, and the median sacral artery (effectively a diminutive continuation of the aorta below the iliac bifurcation) play this role at the appropriate segments.

In the cervical spine, the left and right vertebral arteries arise off the first portion of the subclavian artery for each respective side. These arteries are generally unequal in size, with the left the larger and dominant of the two. The typical course of the vertebral artery allows for its classic division into four segments, V1 through V4. The first segment (V1) starts with the branching of the vertebral artery from the subclavian artery and follows as it travels anterior to the transverse foramen of C7 and into the transverse foramen of C6. The second segment (V2) includes the section of the artery as it passes through the successive vertebral foramina from C6 to C1. V3 comprises the portion from the superior aspect of the arch of the atlas to the foramen magnum; (V4) extends from the foramen magnum to the confluence with the contralateral vertebral artery and together they form the basilar artery. The upper cervical cord segment is supplied from the left C5/6 level, while the inferior cervical cord from the right C4/5 segment. The lower portion of the cervical anterior spinal artery is fed via the left C5/6 radiculomedullary contributor, which also happens to supply the posterior spinal artery network; the upper anterior spinal artery segment is fed by the right C4/5 radiculomedullary artery (Figs. 2.10A and B).

The artery of thoracic enlargement (*Adamkiewicz*) usually comes of T9 through T12 regions.²⁶ There is often a region of the thoracic cord (depending on the level of the Adamkiewicz origin) that is rather small in caliber, relative to the more well-developed cervical region vessel.

Figs. 2.10A and B: (A) Sagittal and (B) axial views of venous system of the vertebra.

A “watershed” of sorts therefore exists that occasionally may correspond to cord infarction in states of hypotension. The Artery of Adamkiewicz can occasionally (25% of the time) come off unusually high or low.

The terminal region of the cord, *conus medullaris*, is quite vascular. It is usually visualized as an arterial “basket,” consisting of the anterior spinal artery and two “posterior” spinal arteries, which are anastomosed at the bottom of the conus. Multiple radicular arteries, supplying the nerve roots of the cauda equina, are usually passed through the basket (unlike the rest of the cord, where radicular arteries are usually visualized via segmental arterial injections, and normally flow toward, rather than away, from the cord).

The *median sacral artery*—a continuation of the aorta,³⁰ the median or middle sacral artery usually comes off the bifurcation. As a homolog of the aorta, it gives origin to segmental vessels of the sacrum. *Lateral sacral arteries*—they are longitudinal vessels that are homologous to the paravertebral (pretransverse) anastomoses in the thoracolumbar segments and to the vertebral artery in the cervical spine. They arise from proximal internal iliac arteries.

Gilbert Breschet in 1819 provided the first detailed anatomic description of the vertebral venous plexus.²⁸ The vertebral *venous system* can be divided into three components—the intradural (extramedullary and intramedullary veins), extradural (epidural), and intraosseous /paraspinal veins. Classically, the names are anterior external, anterior internal, posterior internal, and posterior external venous plexuses, corresponding to intradural and extradural networks. The veins are a capacitance network—about 75% of intracranial blood pool at any given time is situated in

the veins. The same probably goes for the spinal cord, if not more. The intramedullary and extramedullary systems are highly redundant and therefore fail only under extreme circumstances.

The spinal cord is drained by a redundant, centripetally arranged venous network that extends to the cord surface in a semi-organized fashion. These intramedullary veins (also known as radial veins) are angiographically invisible in normal state. Once on the surface, the spinal veins are organized in a loose network that is much more distributive than the arterial system. Anterior and posterior longitudinal spinal veins are described; these run along the length of the cord in an interconnecting fashion, and go by various names such as “anterior and posterior coronal veins”; the anterior vein may pass for a discrete entity and may be called “anterior median spinal vein,” but variability is the rule.

The internal venous plexus has been extensively studied and is located within the epidural space.²⁹⁻³¹ The internal vertebral venous plexus consists of four interconnecting longitudinal vessels, two anterior and two posterior. The external vertebral plexus (EVP), in contrast, lies peripheral to the vertebrae and is made of the anterior and posterior EVPs.³² The EVP is situated anterior to the vertebral bodies and in relation to the laminae, spinous processes, transverse processes, and articular processes, respectively. These veins communicate with the segmental veins of the neck, the intercostal, azygos, and lumbar veins. With the veins of bones of the vertebral column, the internal and external EVPs form Batson’s plexus.²⁹ These veins are predominantly located in the anterolateral part of the epidural space, and

Figs. 2.11A and B: (A) AP view computed tomography (CT) angiogram showing the vertebral artery course. (B) PA view CT angiogram showing the vertebral artery course.

ultimately drain into the azygos system of veins. As the whole system is valveless, increased intrathoracic or intra-abdominal pressure can lead to major congestion and vessel enlargement within the spinal canal. The epidural venous plexus is surrounded by sparse quantity of fat. The anterior epidural space is entirely occupied by a rich venous plexus (Batson's plexus). The plexus communicates with the intracranial sigmoid, basilar venous sinuses, basivertebral vein, occipital vein, and the azygos system. The plexus is linked to the abdominal and thoracic veins by the IV foramina and through this connection transmit intra-abdominal and intrathoracic pressure to the epidural space. The rich venous plexus is also connected to the iliac veins through the sacral venous plexus (Figs. 2.11A and B).

FUNCTIONAL ANATOMY/ STRUCTURAL SPINAL STABILITY

Overview and Definition of Terms

The functional spinal unit (*FSU*) is the smallest physiological motion unit of the spine to exhibit biomechanical characteristics similar to those of the entire spine. An *FSU* consists of an inferior and superior vertebral body and all of the connective soft tissues between them.³³ Contractile and nervous tissues are excluded. When the motion of an *FSU* lies within an anatomical plane of the vertebral coordinate system, the planar motion is relatively straightforward to describe. Planar motion is often a combination

of rotation and translation. One approach to describing planar motion is to define a rotation angle and a center of rotation (*COR*). These two variables completely describe any planar motion. Throughout a range of motion, the *COR* may be fixed or may move with the degree of motion. When the motion of an *FSU* is not planar, describing the three-dimensional motion completely is nontrivial. The mechanical behavior of the *FSU* is described by the relation between the applied load and resulting motion and this relation is often nonlinear.

Range of motion is the motion that occurs between the limits of the applied load “the entire range of the physiological IV motion, measured from the neutral position.” It is divided into two parts: neutral and elastic zones.

Stiffness (*K*) is the slope of the load-motion curve (units N/mm or Nm/deg). It is important to define at which point on the curve the stiffness is calculated. Typically it is defined in the secondary region of the curve where stiffness is constant over that range.

Neutral zone is the zone of high flexibility; it is that part of the range of physiological IV motion, measured from the neutral position, within which the spinal motion is produced with a minimal internal resistance.³⁴

Motion

The movements permitted in the vertebral column are flexion, extension, lateral movement, and rotation.

The spinal muscles function to stabilize and achieve movements of the vertebral column. A number of muscle groups act on the spine. Those located anterior to the vertebral bodies act as flexors. These include longus capitis and colli, psoas major, and rectus abdominis. Lateral flexion is achieved by the scalenes in the cervical region and quadratus lumborum, transversus abdominis, and the abdominal obliques in the lumbar region. The flexors and lateral flexors of the spine are innervated by the ventral rami of spinal nerves.

In contrast, the extensors of the spine are located posterior to the vertebral bodies and are innervated by the dorsal rami of spinal nerves. The term “spinal muscles” typically refers to the extensors of the spine.

In flexion, or movement forward, the anterior longitudinal ligament is relaxed, and the IV fibrocartilages are compressed in front, while the posterior longitudinal ligament, the ligamenta flava, and the inter- and supraspinal ligaments are stretched, as well as the posterior fibers of the IV fibrocartilages. The interspaces between the laminae

are widened, and the inferior articular processes glide upward, upon the superior articular processes of the subjacent vertebrae. In general, this motion increases the cross-sectional area of the spinal canal. Flexion is the most extensive of all the movements of the vertebral column, and is freest in the lumbar region.

In extension, or movement backward, an exactly opposite disposition of the parts takes place. This movement is limited by the anterior longitudinal ligament, and by the approximation of the spinous processes. It is freest in the cervical region.

In lateral movement, the sides of the IV fibrocartilages are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments. This movement may take place in any part of the column, but is freest in the cervical and lumbar regions.

Rotation is produced by the twisting of the IV fibrocartilages; this allows a considerable extent of movement when it takes place in the whole length of the column, although only slight between any two vertebrae. The extent and variety of the movements are influenced by the shape and orientation of the zygapophyseal joint articular surfaces. Thus, facet joints can be said to act like railway tracks, guiding the movements of the spine. In the *cervical region*, the upward inclination of the superior articular surfaces allows free flexion and extension. Extension can be carried farther than flexion; at the upper end of the region, it is checked by the locking of the posterior edges of the superior atlantal facets in the condyloid fossae of the occipital bone; at the lower end, it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic. Flexion is arrested just beyond the point where the cervical convexity is straightened; the movement is checked by the opposition of the projecting lower lips of the bodies of the vertebrae with the shelving surfaces on the bodies of the subjacent vertebrae. Lateral flexion and rotation are free in the cervical region; they are, however, always combined. The upward and medial inclinations of the superior articular surfaces impart a rotary movement during lateral flexion, while pure rotation is prevented by the slight medial slope of these surfaces.

In the *thoracic region*, notably in its upper part, all the movements are limited in order to reduce interference with respiration. The almost complete absence of an upward inclination of the superior articular surfaces prohibits any

marked flexion, while extension is checked by the contact of the inferior articular margins with the laminae, and the contact of the spinous processes with one another. The mechanism between the seventh cervical and the first thoracic vertebrae, which limits extension of the cervical region, will also serve to limit flexion of the thoracic region when the neck is extended. Rotation is free in the thoracic region: the superior articular processes are segments of a cylinder whose axis is in the mid-ventral line of the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum.

In the *lumbar region*, flexion and extension are free. Flexion can be carried farther than extension, to just beyond the straightening of the lumbar curve; it is, therefore, greatest at the lowest part where the curve is sharpest. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebrae, and on this account a considerable amount of lateral flexion is permitted. For the same reason, a slight amount of rotation can be carried out, but this is so soon checked by the interlocking of the articular surfaces that it is negligible, and that is why the axis of rotation of a lumbar vertebra lies close to the base of the spinous process.

Spinal Stability

It is the most clinically important biomechanical parameter, but also the most elusive. From an engineering perspective, a system is said to be stable if it returns to its initial state after a perturbation. With an axial compressive load of >20 lbs, the ligamentous lumbar spine is unstable; it cannot remain upright and buckles. Thus, the musculature of the spine is essential in maintaining spinal stability. Leonardo da Vinci was the first bioengineer to appreciate this instability and hypothesized that the musculature of the spine performed in the same way as the guy wires of a ship's mast. White and Panjabi, in their text, provided a more clinical definition of spinal stability: "the ability of the spine under physiological loads to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots and, in addition, to prevent incapacitating deformity or pain due to structural changes..." There are quantitative guidelines that are typically specific measurements, beyond which the spine is felt to be unstable. Many of these will be further discussed in the pertinent chapters to follow.

Figs. 2.12A and B: (A) Standing sagittal view of the spine. (B) Standing coronal view of the spine.

Spinal Balance

The concept of spinal balance is based upon the principle that overall function and upright posture is most efficient when the skull, and the rest of the upper body mass, is centered over the pelvis. Dubousset described this concept as the “cone of balance” or cone of economy.³⁸

In the coronal plane, this effect is achieved through body symmetry. In order to achieve the same effect in the sagittal plane, the spine presents several closely related curves, which correspond to the different regions of the spinal column, and are called cervical, thoracic, lumbar, and pelvic. Curves that are convex ventral are described as lordotic curves, and curves that are convex dorsal are described as kyphotic (Figs. 2.12A and B). The *cervical* curve, which is normally lordotic, begins at the apex of the odontoid process, and ends at the middle of the second thoracic vertebra; it is the least marked of all the curves. The *thoracic* curve, which is kyphotic, begins at the middle of the second and ends at the middle of the 12th thoracic vertebra. Its most prominent point behind corresponds to the spinous process of roughly the seventh thoracic vertebra. The *lumbar* curve is more marked in the female than in the male; it begins at the middle of the last thoracic vertebra, and ends at the sacrovertebral angle. It is lordotic, the convexity of the lower three vertebrae being much greater than that of the upper two. The *pelvic* curve begins at the sacrovertebral articulation, and ends at the point of the coccyx; its concavity is directed downward and forward. The thoracic and pelvic curves are termed primary curves, because they alone are present during fetal life. The cervical and lumbar

curves are compensatory or secondary, and are developed after birth, the former when the child is able to hold up its head (at 3 or 4 months), and to sit upright (at 9 months), the latter at 12 or 18 months, when the child begins to walk.

The vertebral column has also a slight *lateral* curvature, the convexity of which is directed toward the right side. This may be produced by muscular action in right-handed individuals, especially in making long-continued efforts, when the body is curved to the right side. In some patients who are left-handed, the convexity aims to the left side. A competing theory suggests that this curvature is produced by the aortic arch and upper part of the descending thoracic aorta—a view that is supported by the fact that in cases where the viscera are transposed and the aorta is on the right side, the convexity of the curve is directed to the left side.

The degree to which the spinal balance is assigned in reference to the sagittal plane is defined as the plumb line and its relationship to axis of rotation about the hip; this concept makes assessment of both hip positions on the standing sagittal film very important. Ideal balance is referred to as a plumb line from the center of C7 to within 2 cm from the posterior superior aspect of the sacrum.

Pelvic parameters include pelvic incidence (PI), sacral slope (SS), and pelvic tilt (PT). *Pelvic incidence* is defined as the angle between the perpendicular to the sacral endplate at its midpoint and the line from that point to the midpoint of femoral head axis. It is clinically relevant for its correlation to the optimal lordosis ($PI \approx LL + 9^\circ$). *Sacral slope*: angle between the sacral endplate and the horizontal. *Pelvic tilt*: angle between the line connecting the midpoint of the sacral endplate to the femoral head axis and the vertical. The PI is equal to the sum of the SS and the PT (Fig. 2.13).^{35,36}

Thoracic kyphosis is measured from the superior endplate of T4 to the inferior endplate of T12. *Lumbar lordosis* is measured from the superior endplate of L1 to the superior endplate of S1.

While significant debate exists about how to best define ideal global spinal balance, it is determined by the thoracic kyphosis, the lumbar lordosis, their relationship to each other, and the PI at the base of the spine. While neither normative values for ideal cervical lordosis in the adult population, nor the best parameters for defining cervical alignment have been clearly identified, a growing body of evidence suggests that balance in this portion of the spine, too, contributes to both global spinal balance and overall function.³⁹

Fig. 2.13: Spinopelvic parameters.

CONCLUSION

The spinal column serves several functions: protect the neural elements, provide upright structure, and allow enough mobility for locomotion and interaction with our environment. The structure needed to achieve both these complimentary and contradictory missions results in a highly complex entity. The anatomic relationships described here play a critical role in normal and pathologic states of the spine, and in the surgical and nonsurgical management of these states.

HISTORY

The biomechanics of the spine have been researched and written about for thousands of years to answer questions about how and why we move and become injured. The first documented appreciation for the spine and spinal anatomy was from the ancient Egyptians. Due to their in-depth knowledge of the process of mummification, they possessed a basic understanding of the spine and associated connections in the body. In the ancient papyrus that Edwin Smith brought to England, there were descriptions from 1700 BCE of head and spine diseases in 48 patients detailing examination, diagnosis, and treatment.¹

The *Iliad*, written by Homer around 700 BCE, was the next surviving text to relate an appreciation of spinal cord injury. When Hector was killed during the Trojan War after a sword pierced him in the neck, Homer described him as going limp. The story was referring to an injury to his spinal cord causing paraplegia.² Later, Hippocrates, who lived in 400 BCE and wrote about the spine, discovered basic methods for biomechanical corrections of deformities, including simple rope and weight devices. Through extensive studies, he also divided the spine into three separate parts: above the clavicle, at the chest level, and below the chest.²

During 1000 CE, Avicenna was a Persian anatomist and philosopher who made great contributions to the study of spinal biomechanics. In *The Book of Healing*, he developed

an elaborate theory of motion. As a physician, he studied the spine in great detail and came to understand the mechanical movements between the skull and spine.³ He also wrote about the anatomy of the nervous system, although this work was mainly Galenic in origin.⁴ In the late 1400s, Leonardo da Vinci, the great scientist, painter, and inventor, performed extensive research and completed the first anatomically correct sketches of the spine. He acquired a detailed understanding of biomechanics and described an analogy likening the spinal column to the mast of a ship.⁵

Shortly thereafter, in the 1600s CE, Giovanni Borelli published the first extensive report linking the structure of the spine to the functional mechanics of movement. Through investigations of the connections between muscles and joints, he was able to calculate the center of gravity of the human body. As a result of his integration of biology with mechanical properties, he is commonly referred to as the “Father of Biomechanics.”⁶

During the 1800s and 1900s, great advances were made when hanging became the preferred method of exacting justice. This common practice led to a better understanding of the biomechanical stresses and fractures related to injuries to the spine and spinal cord. Later in the 20th century, with the explosion of advanced physics, modern medicine, and computer technology, the knowledge of the spine and the body as a whole has grown exponentially.

SPINAL ANATOMY

The spine is a structure of bone and cartilage consisting of vertebrae connected by intervertebral discs and closely related nerves, veins, arteries, and lymphatic vessels. The 33 vertebrae are divided into four groups based on their location and physical properties. From cephalad to caudal, there are seven cervical vertebrae (C1–C7), 12 thoracic vertebrae (T1–T12) that are supported by connections to the rib cage, five lumbar vertebrae (L1–L5), and five sacral and four coccygeal vertebrae that are fused and immobile.⁷

These regions normally exhibit distinct forms of curvature. The cervical and lumbar regions have a primary lordotic curve, with the concavity posteriorly, while the thoracic and sacral spinal vertebrae make up a kyphotic curve, in which the concavity is located anteriorly. This undulating pattern of alternating curve directions is best demonstrated when standing erect, and helps the body assume various positions such as sitting and lying down (Fig. 3.1).⁸

Functional Unit of the Spine

The functional unit of the spine consists of two bony vertebrae and the cartilaginous disc between them, as well as the adjoining ligaments. Also termed a motion segment, this combination of bone and fibrocartilage functions as a unit and exhibits the characteristic biomechanics of the entire spine. Although closely associated with muscle, nerves, and vessels, these structures are not considered a part of the biomechanical functional unit.⁸

Fig. 3.1: Spinal functional unit and curvature.

Bone

The bony part of the spine is called the vertebra. The vertebrae are typically described as comprising multiple distinct parts. The largest part, the body, is the weight-bearing portion of the spine and is attached to the cartilaginous discs. Attached posteriorly is the vertebral arch, a thin, strong structure consisting of the pedicles, transverse processes, and lamina, with the singular spinous process protruding posteriorly. This arch forms the vertebral foramen that can be thought of as a hollow canal that protects the spinal cord (Fig. 3.2).⁹

Disc

The intervertebral disc connects two vertebral bodies. This cartilage-like component serves an essential role as a shock absorber for the human body and makes possible the range of motion of the spine. There are two main parts of the disc. The first is the inner nucleus pulposus, which consists of a gelatinous substance of collagens and normally water-laden glycosaminoglycans, and serves the purpose of absorbing most of the axial energy. Surrounding and containing this is the annulus fibrosis, a thicker fibrous layer composed primarily of collagen fibers.^{10,11}

Ligaments and Tendons

Tendons and ligaments connect muscle to bone and bone to bone, respectively, and enable the musculature to move our bodies. Ligamentous and tendinous connections permit motion of spinal joints and augment the overall strength and stability of the spine. The anterior longitudinal ligament runs along the entire length of the spinal column and is attached to the anterior aspect of each vertebra and disc

Fig. 3.2: Anatomy of a spinal vertebra.

Fig. 3.3: Anatomy and structure of spinal column ligaments.

(Fig. 3.3). The posterior longitudinal ligament also spans the entirety of the spinal column, posterior to the discs and vertebral bodies. On the posterior arch, the laminae are each linked by individual ligamentum flavum. These ligaments collectively serve to protect the spinal cord while permitting movement of the spine. By serving as a check-rein once a maximum tension in the direction of their fibers has been reached, ligaments prevent hypermobility of the vertebral canal, thereby protecting the spinal cord and spinal nerves.⁸⁻¹⁰

BIOMECHANICS OF THE SPINE

The spine is a highly complex biomechanical structure that can be described using a combination of simple fundamental biomechanics as well as more complex functional biomechanics. In addition, each region of the spine is unique in its biomechanical properties.

Fundamental Biomechanics

Physics

A firm grasp of the physical sciences is important for comprehending the biomechanical properties of the human body, and for this reason the following few concepts are indispensable. An appreciation for momentum, Newton's first and second laws, and Hooke's law contributes to a more fundamental understanding of the mechanical properties of the spine.⁹

Momentum and Force

Momentum is the product of the scalar quantity mass and the vector quantity velocity. An appreciation for the effect of momentum on biomechanics can be better related through Newton's first law, which states that an object at motion will stay at motion until acted upon by an outside force. Physical entities within the spine are able to provide the reactive force necessary to maintain the spine in a stable position. Newton's second law states that the net force vector of an object is equal to the product of the scalar mass and the net acceleration vector. This explains that, although many forces may be acting on a single object, all of the vector forces can be combined into a resultant force vector. Newton's third law holds that for every force there is an equal and opposite reaction force. The internal mechanistic properties of the spine must equal and withstand any external force applied, or there will be a rupture, or break in a spinal element.⁹

Hooke's Law

Hooke's law is of great importance in relation to biomechanics. This tenet holds that when a force or stress is applied to an object, there is a degree of deformation or strain on that object when within the elastic zone. This concept can be extended and graphically represented with a stress-strain curve, describing the biomechanical properties and possible deformation capability. The curve starts with a neutral zone in which stress is applied, yet no deformation is observed. This is due to energy being dissipated from one part of the body into others, such as from the vertebra to the adjacent soft tissues. After exceeding the neutral zone, the elastic zone is reached, in which the extent of deformation of the entity is proportional to the strain applied. According to Hooke's law, the stress-strain curve for the elastic zone should be linear in nature, and it is referred to as elastic because once the strain is removed, the shape returns to its neutral state. However, this law further holds that the deformation of an entity can reach a critical level, in which deformation is no longer elastic, and permanent or "plastic" deformation is incurred.⁹ This is often observed clinically when a patient presents with joint laxity or hypermobility of a skeletal segment.

Force and Movement Definitions

Types of forces: The spine is a robust structure that can withstand a multitude of complex forces, and each type

Fig. 3.4: Represents different forces that can be applied to the spinal column including shear, torsion, and tension.

of force may result in a different reaction. At any one time there may be multiple forces acting upon the spine, and what a person feels is the combined resultant force.¹¹ The four basic forces are torsion, tension, compression, and shear forces. The biomechanical properties of the spine and all contributing anatomy provide for great resistance to these influences (Fig. 3.4).^{8,10}

Coupling motion: Motion coupling is a phenomenon that is demonstrated throughout the human body and the spine is no exception. Coupling occurs when one type of motion induces a compensatory motion in a different plane along a different axis. The intended movement is referred to as the main motion, while the secondary movement is the coupled motion. This is an important biomechanical concept, especially important in the spine because it illustrates how spinal anatomy functions when in motion, and how forces move through the spine.^{8,12}

Each part of the spine has unique geometry, and the coupling patterns differ between the cervical, thoracic, and lumbar regions. The best example of coupling occurs in the cervical spine. When the cervical region bends, there is resultant coupling and secondary cervical rotation to the opposite lateral side.^{8,13} Coupling in the lumbar spine occurs during side bending as well. Similar to the cervical spine, side bending is coupled with axial rotation; however, in the lumbar region, rotation is in the same direction as side bending. The upper thoracic spine exhibits this side-bending-rotational-coupling phenomenon similar to the cervical region, while the lower thoracic spine displays very little coupling.^{8,11,14}

Functional Biomechanics

Range of Motion and the Neutral Zone

The spine exhibits a nonlinear load displacement curve. This curve can be seen as two separate and distinct regions

Fig. 3.5: Graph is displaying displacement vs load for the full range of motion (ROM) of the spine. As demonstrated, the neutral zone is the area of low load and resistance on the spine. The area beyond the neutral zone, but still within the ROM, is known as the elastic zone.

with unique qualities—the neutral zone and the elastic zone. The neutral zone is the arc in which the spine exhibits the maximum flexibility with minimal increase in tension, and corresponds to the initial range of motion. The spine experiences relatively low stresses within the neutral zone. The second portion of the load displacement curve is the elastic zone. This is reached when the motion causes the spine to move beyond the neutral zone of least resistance. The elastic zone encompasses the limits of range of motion and the anatomy is subject to much higher internal resistance (Fig. 3.5).^{15,16}

If the neutral zone were to be expanded, there would be increased laxity (ligamentous, muscular, etc.) in motion segments and the elastic zone would be relatively smaller. Having a smaller elastic zone would increase the demands on the stabilization system of the spine. The stabilization of the spine is comprised of the anatomical structures contributing to passive, active, and neutral support. If the neutral zone was larger, the stresses exerted on the body due to internal resistance would increase greatly. This increase would ultimately bring about instability due to the increase in internal forces over a smaller range of motion. The neutral zone appears to be a clinically important measure, and some studies have shown that the size of the neutral zone may be a better indicator of spinal instability than the total range of motion.¹⁷ The neutral zone may be increased by weakness of the paraspinal muscles, or with injury, and decreased by surgical fixation or through processes such as osteophyte formation.¹⁵

Table 3.1: Cyclic loading with various loads increases the rate of failure of the lumbar spine.

	Relative load (%)		Number of loading cycles		
	10	100	500	1000	5000
60–70	10%	55%	80%	95%	100%
50–60	0%	40%	65%	80%	90%
40–50	0%	25%	45%	60%	70%
30–40	0%	0%	10%	20%	25%
20–30	0%	0%	0%	0%	10%

Cortical Shell

The cortex is a thin layer of compact, hard bone surrounding the porous trabecular bone of the vertebral body. Although only a small portion of the total vertebral body, the cortex exhibits certain biomechanical properties that make it very important for spinal function. With advances in technology, computed tomography scans of vertebral bodies have enabled finite element analysis experimental models to be constructed and used to predict failure loads and fracture patterns.¹³ One such model was axially loaded to the failure point, and found a wide variation in the load-bearing capacity of the cortical shell, supporting anywhere from 12% to 75% of the total compressive load.^{18,19}

Regional Biomechanics

Cervical Spine

The cervical spine is unique in that, while one end is connected to the spine below, the other end articulates with the skull. The cervical spine is associated with the most mobility of any region, and this is due to a combination of flexion/extension, axial rotation, and lateral bending capabilities. In particular, the occiput-C1 articulation has the greatest combined flexion extension capacity with 25° total motion. The C1–C2 articulation accounts for approximately 40° of axial rotation, nearly half of the total rotation for the entire cervical region. The mid-cervical joints permit the greatest lateral movement of the spine as well. The relative paucity of structural support and constraints to motion in the cervical region allows for a high degree of mobility, but also makes the cervical spine especially vulnerable to destabilizing injuries (Table 3.1).⁷

Thoracic Spine

Although one of the strongest and most stable parts of the spine, the thoracic spine exhibits a relatively limited

range of motion due to the articulations with the ribs. The axial rotation of the upper thoracic region is significantly greater than the lower thoracic region. In addition, the thoracic spine is biomechanically unique in that the degree of possible side bend is roughly equivalent for each vertebral level (Table 3.1).⁷

Lumbar Spine

Situated at the caudal end of the spine, the lumbar spine must support the entire load from above. This section is comprised of the five largest vertebrae in the human body, and the increased diameter helps to distribute the force of this large portion of bodyweight.⁷ The lumbar region exhibits relatively less mobility than the cervical region and more than the thoracic. One unique biomechanical feature of the lumbar spine is the very limited rotational capability. This is because, in contrast to the cervical region, the lumbar spine has facet joints oriented in the sagittal plane, which restrict axial rotation (Table 3.1).

TRAUMA

The amount of tissue damage is a direct result of the direction, magnitude, and temporal qualities of the forces applied. According to Herkowitz et al.,⁸ there are three main types of pathological loadings of the spine. Each type results in a unique and specific response and causes varying degrees of damage. The first and most common type is acute trauma, which describes a situation in which one force is able to surpass the load-bearing capabilities of the tissue leading to injury. The second type is cumulative trauma, a gradual weakening of the tissue capacity due to repetitive loading. The final type is instability, defined as abnormal displacement of a spinal segment leading to pain.⁸

Acute Trauma

Acute trauma is caused by large forces that exceed the biomechanical limits of the spine leading to soft tissue failure. The specific pattern of injury depends heavily on the magnitude and direction of applied forces. One injury type, termed as burst fracture, is due to high intensity compressive forces on the spine. The most common compression injury involves increased pressure within the disc nucleus to the extent that the outward force on the adjacent vertebra pushes the endplate into the vertebral body. This can lead to small fractures of the trabecular bone, posterior cortical bone, and the end plate itself.¹¹ A second type of acute injury, a flexion-distraction injury, is due to a rapid forward bending movement producing a force greater than the elastic limit of the posterior ligamentous complex, leading to failure of the posterior elements.²⁰ A third acute injury, extension-distraction, is caused by hyperextension through a spinal segment. This can cause damage to the disc or vertebral body and may also damage

the posterior elements in severe cases. The final type of acute spinal injury is translational, in which shear or distractive forces lead to a highly unstable spine, and is frequently associated with injuries to the neural elements.¹¹

Cumulative Trauma

This spinal injury category is caused by repetitive forces. These repetitive forces are able to gradually damage and destroy the stabilizing structures of the spine. This long-term weakening is due to microtrauma leading to tissue injury and eventually structural compromise and failure. In contrast to acute trauma, failure from this type of trauma can potentially be avoided through lifestyle modification or alteration of training and exercise patterns. Recognition of the ongoing injury and allowing time to rest between exposures may let the body recover and can actually increase the strength of the tissue rather than leading to injury (Table. 3.2).^{8,11,21}

Table 3.2: Range of motion of different spinal segments for different types of movement including flexion/extension, lateral bending, and axial rotation.

Source: Adams M, Bogduk N, Burton K, et al. The Biomechanics of Back Pain (Second ed.). Churchill Livingstone; 2006.

Instability

Finally, instability of the spine due to repeated supra-physiologic motion causes deformation of the structures that usually limit motion. Abnormal displacement of these structures may be very small, but is often enough to stimulate pain receptors in facet joints, disc structures, and other associated soft tissue structures.^{8,11}

Mechanical Trauma

Any type of loading force can lead to tissue damage within the spine. Although disc injuries are more common than bone injuries, the bony vertebra can fail in a variety of ways. The normally strong bone is often weakened by other factors, such as malignancy, electrolyte imbalance, and decalcification, or poor nutrient supply, prior to the fracture.⁸ Vertebral fractures are typically associated with major trauma and can result in spinal cord injury and neural damage. As already mentioned, compression and burst fractures are due to high-energy axial loading, and often involve bone fragments penetrating the surrounding tissues and sometimes the spinal canal. Another injury type pertains to fractures of the posterior elements such as the pedicles and facet joints. These injuries or a combination of injury types can sometimes lead to pathology such as spondylolisthesis, or the slippage of one vertebral body on another.

A new classification and injury severity system for traumatic fractures of the thoracolumbar spine has recently been proposed based on morphologic identification of these injury patterns and associated neurologic injury as well as several clinically relevant modifiers. Studies are underway to validate this system on a worldwide basis. It is hoped that this system will provide a universally accepted method of discussing such injuries and also provide guidance to the surgeons treating them.²²

KEY POINTS

- *Functional unit of the spine:* A motion segment is the smallest physiological unit of the spine to exhibit biomechanical characteristics similar to those of the entire spine.¹² The functional spinal unit consists of two vertebral bodies separated by a cartilaginous disc, and all adjoining ligaments. This motion segment is, in itself, responsible for many of the attributes and abilities of the spine. Because the load-displacement

curve is similar, one or more functional spinal units are often used to model the spine and to measure its biomechanical properties.

- *Regional biomechanics:* Each distinct segment of the spine exhibits unique characteristics due to differences in the structures of the vertebrae, ligaments, and discs. The cervical spine is capable of the most flexibility due to combined flexion extension, axial rotation, and lateral bending. The thoracic spine demonstrates the most stability and the least mobility. Finally, the lumbar spine experiences somewhat more motion than the thoracic region yet not nearly as much as the cervical spine.
- *Spinal trauma:* Pathological loading can be divided into acute trauma, cumulative trauma, or instability categories. Examples include compression, flexion-distraction, extension-distraction, and translational mechanisms. The associated fracture patterns and treatment needs vary widely by injury type and severity.
- *Coupling motion:* Coupling is when one motion in one part of the spine induces an associated movement in a different part of the body. This is an important concept in biomechanics because it demonstrates how forces pass through the spine, and provides insight into anatomic constraints to the range of motion.

INTRODUCTION

Current spinal instrumentation techniques broadly range from rigid fixation, used to enhance fusion rates or treat segmental instability, to dynamic stabilization, designed to improve stability, while maintaining some mobility at the spinal motion segment. Anterior plating is the standard in the subaxial cervical and lumbar spine, while screw/rod constructs are utilized in the posterior cervical and thoracolumbar spine. Various options are available for each, and different designs or insertion techniques have different advantages. Furthermore, fusion constructs are hypothesized to affect the adjacent motion segment, leading to breakdown or degeneration. Recent basic science and clinical research studies have investigated various types of motion preservation implants that may minimize remote mechanical effects. This chapter will discuss the mechanical effects of rigid and motion-preserving implants used in the cervical, thoracic, and lumbar spine.

OCCIPITOCERVICAL FIXATION

Occipitocervical instability stems from a multitude of etiologies including trauma, neoplasm, degenerative arthritis, inflammatory disease, congenital anomalies, iatrogenic causes, and infection. Extension of instrumentation to the occiput is often needed for failure of prior instrumentation, pseudoarthrosis of atlantoaxial stabilization, or basilar

invagination after C1-2 fixation. Unfortunately, fixation from the occiput to the cervical spine usually extends to at least C2, which results in fusing the joints accountable for 50% of flexion/extension and axial rotation of the neck at the occipitoatlantal and atlantoaxial joints, respectively. Extension of the fusion below C2 into the subaxial cervical spine further reduces the range of motion, though to a lesser extent compared to the losses occurring from fusion in the upper cervical spine.¹

Fixation techniques have evolved from wire and rod constructs to occipital plates to plate and screw/rod techniques. Regardless of the technique chosen, it is imperative to have adequate stability to facilitate fusion. Early fixation techniques utilizing cerclage wires required the use of halo application postoperatively to augment the construct. With advancements in fixation, some surgeons now only utilize a hard cervical collar for a brief period after surgery.

Occipital screw placement is one aspect of construct design to consider. Options include plates designed for all midline screws versus screws placed laterally or even fixation to the occipital condyles. Midline placement of screws allows greater length screws compared to more laterally based constructs, which theoretically give strength to the construct at the sacrifice of less space for screws (Fig. 4.1).^{2,3} Medially versus laterally placed screws did not have a significant effect on stiffness of the construct in flexion/extension and rotation, but lateral bending was reduced with

Fig. 4.1: Occiput to C3 fusion completed with three midline screws and bilateral C2 pedicle and C3 lateral mass screws.

laterally placed screws.^{2,4} Recently, new techniques of fixation to the occipital condyles have been of interest if pathology around the occiput does not allow fixation to the area around the inion or if fixation there has already failed. Biomechanical analyses suggest that fixation utilizing the occipital condyle may provide sufficient strength.⁵⁻⁷

Occipital plating offers significantly more stiffness in a construct compared to the original wire and rod constructs. However, plating requires bending the plates in multiple planes for appropriate contouring and significant rod bending that may weaken the ultimate strength of the rods. Recent implant designs include precontoured rods, which are stronger than those contoured on the field. Occipital/pedicle screw and rod constructs have been found to have higher flexion/extension, lateral bending, rotational, and translational stiffness over wire constructs with or without plates.^{8,9}

Regarding cervical fixation of an occipitocervical construct, cadaveric studies investigating fixation of C1/2 transarticular screws, C1 lateral mass/C2 pedicle screws, and C2 lamina screws in occipitocervical fixation found no difference, suggesting that the technique most suitably based on the patient's anatomy and surgeon's comfort be utilized.¹⁰⁻¹² Wolfla et al. compared the presence and absence of C1 lateral mass screws in occipitocervical fixation in constructs with C2 pars screws, C1/2 transarticular screws, and C2 intralaminar screws.¹³ The addition of the C1 lateral mass screws only made a significant enhancement of fixation in the construct with C2 intralaminar screws. Additionally, the strongest construct in this study was the

use of C1/2 transarticular screws, but the authors also report that the strength of all tested constructs is likely strong enough and therefore up to the surgeon.¹³

In summary, occipital plate connected to rod/screw constructs provides the best fixation for occipitocervical fusions. Instrumentation to C1 may be omitted without significantly compromising fixation strength. Surgeons should use fixation to C1 and C2 according to their preference and the patient's anatomy.

■ ATLANTOAXIAL FIXATION

Surgical stabilization can occur by anterior screw fixation of the odontoid fracture or posterior C1-2 fusion and instrumentation.

Anterior Odontoid Screw Fixation

Fixation of odontoid type II and high type III fractures is often done because of increased risk for displacement and nonunion, compared to type I fractures that are inherently stable. The two common fixation choices are ORIF and posterior spinal instrumented fusion. ORIF with screw fixation is commonly utilized for fractures, particularly in younger patients, and allows some preservation of motion of the C1/2 joint. However, the surgical technique can be challenging, and biplane fluoroscopy is required. Successful stabilization not only depends on good bone purchase, but also requires anatomic reduction and compression across the fracture. There is some controversy as to whether a single screw is adequate or a two-screw construct is needed for solid fixation (Figs. 4.2A and B). Intuitively, a two-screw construct would provide more torsional control of the fracture and improved bending stiffness. However, a cadaveric model by McBride et al. comparing two 3.5-mm cannulated screws to one 4.5-mm Herbert screw did not find that the two cannulated screws provided beneficial fixation in shear or torsional stress.¹⁴ A study by Feng et al. also did not observe any difference in shear or torsional strength between one and two double-threaded screw constructs.¹⁵ In this cadaveric study, bone mineral density did not factor into fixation strength, although ultimate failure was not tested.¹⁵ However, a retrospective review by Dailey et al. showed that 96% of two-screw constructs demonstrated radiographic stability at final follow-up compared to only 56% of single-screw constructs.¹⁶

At times, a patient's anatomy only allows for placement of a single screw. Studies, which have looked at the

Figs. 4.2A and B: (A) Anteroposterior and (B) lateral X-rays demonstrating use of a partially threaded lag screw and a second neutralization screw for osteosynthesis of a type II odontoid fracture.

strength of a single cannulated partially threaded screw compared to a variable angle headless screw, showed increased stiffness and load to failure with the variable pitch screw.¹⁷ For single screw constructs, the mode of failure is anterior screw cutout, though early reports of using a single 4.0-mm screw with smaller core diameter (2.5 mm or less) showed screw pullout or breakage as another mode of failure.^{17,18} A recent cadaveric study showed greater load to failure with the addition of a novel plate, and the mode of failure also changed to posterior displacement of the screw.¹⁹ Unfortunately, screw fixation has been found to be <50% of the strength of an intact dens.^{20,21} With that in mind, bioresorbable screws have been tested in cadavers and been found to have similar strength to that of single metal screws.^{20,21} The mode of failure was different as the bioresorbable screws themselves failed, whereas the metal screws failed by cutout from the bone.²¹ Bioresorbable screws do appear to be strong enough to hold reduction in most patients until callus is formed to stabilize the fracture before resorption begins. Other concerns with this type of fixation are the large inflammatory response elicited by the resorption of the screws and the potential osteolytic response that has been seen in other parts of the body. With the small size of the odontoid in relation to the screw, this is a legitimate concern for use at C2.

Posterior Atlantoaxial Fusion

Multiple techniques for stabilizing the C1/2 articulation have evolved, including wiring, transarticular screws,

and variations of screw/rod techniques. Screw fixation to C1 is either via a lateral mass or transarticular screw. C2 fixation options include pedicle, pars, and laminar screws. Wiring techniques, including Gallie and Brooks-Jenkins, provide significantly less stability and should be augmented with either a halo vest postoperatively or further fixation.²² While the Gallie technique places bone graft on top of the C1 posterior ring and notched over the C2 spinous process, the Brooks-Jenkins technique places two structural grafts bilaterally between the lamina of C1 and C2, with the graft placed under compression, thus increasing stability. If only unilateral fixation can be completed, the Brooks-Jenkins technique provides increased stability and is preferred.²² Pure wiring techniques offer less stiffness and allow greater range of motion, particularly in lateral bending and axial rotation compared to constructs with C1/2 transarticular screws and C1 lateral mass screws/C2 pedicle screw/rod (Harms) constructs.²³ One cadaveric study demonstrated better stability utilizing transarticular screws compared to the Harms construct.²⁴ Augmentation of the Harms construct with polyetheretherketone (PEEK) interbody spacers at C1/2 has additionally been shown to further reduce motion.²⁵ Clinically, however, fewer hardware failures were found with the Harms technique compared to transarticular screws, and a significant reduction in radiographic motion was noted at C1/2, favoring the Harms technique.²⁶ Recently, a novel device has been developed that fits into the C1/2 articulation providing interference fixation and then has a screw into the C1

Fig. 4.3: Due to anomalous vertebral artery, C1/2 arthrodesis accomplished utilizing unilateral Harms construct (C1 lateral mass/C2 pars screw) and contralateral C1/2 transarticular facet screw.

lateral mass and two lamina screws.²⁷ This technique was found to provide equivalent restriction in range of motion compared to the Harms technique.²⁷

Surgeon's experience and patient anatomy should determine the choice between transarticular screws and Harms constructs. This is especially important as aberrant anatomy of the vertebral artery has been cited to be as high as 18%.²⁸ If the vascular anatomy does not allow a normal long pedicle screw in C2, biomechanical analysis has

shown that a short pars screw offers similar immediate fixation strength.²⁴ According to some studies, C2 laminar screws are less stable than the Harms construct, but still restrict motion sufficiently to facilitate fusion.^{24,29} Other studies have shown equivalent stability of the laminar screw and pedicle screw constructs, and therefore strong consideration for their use is supported depending on the present anatomy.^{30,31} In salvage situations, mixing constructs with unilateral transarticular screw and pedicle or laminar screw construct on the other side is biomechanically equivalent (Fig. 4.3).³² Furthermore, instances where the posterior arch of C1 is absent and fusion augmentation with structural bone graft posterior is not feasible, intra-articular cages have demonstrated adequate stability.³³

In summary, decisions regarding posterior fixation constructs of the atlantoaxial joint should be made according to the patient's anatomy and the surgeon's judgment and experience. C1/2 transarticular screws and C1 lateral mass/C2 pars screw/rod construct provide adequate fixation strength; intralaminar screws are sufficient for clinical use and may be used as an alternative (Table 4.1).

SUBAXIAL CERVICAL SPINE

The subaxial cervical spine can be stabilized from an anterior approach with plate fixation, or from a posterior approach, usually using lateral mass screw-rod fixation. Alternatively, a cervical disc replacement can be performed.

Table 4.1: Comparison of biomechanical studies of C1/2 arthrodesis constructs.

Study	Type	Construct comparison	Findings
Vergara et al. ²⁶	Clinical-retrospective	C1/2 TAS to C1LM-C2PS	Less intra- and postoperative complications and less broken screws in C1LM-C2P construct. Similar fusion rate
Savage et al. ³⁰	Cadaveric biomechanical	C1LM with C2IL vs C2PS	No difference in motion after cyclic loading
Melcher et al. ²³	Cadaveric biomechanical	Gallie wiring, C1/2 TAS, C1LM-C2PS	Screw constructs significantly reduced motion compared to wiring (lateral bending, axial rotation); no difference between the two screw constructs
Papagelopoulos et al. ²²	Cadaveric biomechanical	Brooks and Gallie wiring with/without 1 or 2 TAS	Gallie wiring with 1 TAS showed most range of motion and therefore not recommended if only one screw can be placed. No difference in two-screw constructs
Sim et al. ²⁴	Cadaveric biomechanical	C1LM-C2PS (long/short), Gallie wiring, C1LM-C2IL, C1/2 TAS	TAS provided the highest stability. Use of short or long PS in C2 did not affect stability

(PS: Pedicle screw; IL: Intralaminar; TAS: Transarticular screw; LM: Lateral mass).

Anterior Cervical Fixation

Anterior cervical spine surgery is done for numerous pathologies and is one of the most frequently performed approaches for the treatment of subaxial cervical spine disorders. Restoration of lordosis, a frequent reconstructive goal, is biomechanically advantageous as a cadaveric study demonstrated increased load bearing by an anterior cervical plate when lordosis is not restored.³⁵ When faced with a patient with multilevel disease, the decision to do a two-level anterior cervical discectomy and fusion (ACDF) versus a corpectomy arises. Retrospective data evaluated sagittal alignment, cervical lordosis, graft subsidence, and the effects on adjacent levels in patients undergoing single-level corpectomy or two-level ACDF.³⁶ No difference was found between the two constructs, except that the corpectomy tended to have caudal end plate subsidence even after 6 weeks, but this did not affect overall sagittal alignment.³⁶ Hussain et al. in a finite element model showed that multilevel discectomy placed less stress on the bone-screw interface, bone graft, and end plates when compared to two-level corpectomy and was overall stronger.³⁷ However, with a greater number of fusion sites required, there remains concern for a higher rate of pseudoarthrosis.

Long anterior constructs pose different challenges. A cadaveric study showed that three-level discectomy and plate and one-level discectomy and adjacent corpectomy were stronger than a two-level corpectomy stabilized with a plate.³⁸ Setzer et al. supported this in a cadaveric study showing similar stability of a three-level discectomy with plating compared to a two-level corpectomy with plating and posterior fixation.³⁹ In fact, they showed that posterior fixation ultimately provided the best fixation and anterior plating for a two-level corpectomy did not sufficiently add stability.³⁹ However, the authors still recommend anterior plating for a two-level corpectomy to prevent graft dislodgement in the clinical setting.

Anterior cervical plating is offered in static (rigidly locked screws) and dynamic options. Dynamic options include rotationally dynamic plates where the screws are allowed to toggle in the plate and translationally dynamic plates where either the screws can translate in the plate or the plate itself translates. Dynamic plates theoretically allow controlled settling of the construct to optimize fusion incorporation, but subsidence correlates with loss of lordosis.⁴⁰ Brodke et al. simulated graft subsidence and found that the statically locked plate construct failed to

maintain load-sharing characteristics.⁴¹ They also showed that with subsidence and maintenance of the graft end plate interface, there is greater overall stiffness. Hong et al. showed increased graft subsidence and translation in the dynamic plate group, but this did not lead to a difference in fusion rates or clinical results.⁴² A randomized control trial investigated the difference between dynamic and rigid plating and found less plate complications and faster time to fusion when dynamic plates were used, but more loss of lordosis compared to rigid plating.⁴³ With the lower implant complications in the dynamic plating group, they recommend that dynamic plating be the preferred technique. Despite these findings, further investigations are warranted before this should be deemed the preferred plating design.

Screw orientation may also play a role in the biomechanics of the construct. Finite element analysis modeling demonstrates that the more divergent screws become from the plate, the more the construct transitions from a load-bearing device to a load-sharing device with increasing shear forces on the screw and increased forces on the bone graft, end plate, and bone-screw interface.⁴⁴ This remains a theoretical advantage as the neurovascular structures are at increased risk with divergent screw placement.

Stand-alone interbody cages that have screw fixation into the vertebral body are lower profile and eliminate the use of an anterior plate that may cause dysphagia, erosion into the esophagus, and other complications. However, their use has disadvantages. The fixation with screws and the structural integrity of the cage sacrifice space available for bone graft. A cadaveric study comparing a stand-alone anchored cage to locked and dynamic plates with cages found comparable stability and limitation in motion.⁴⁵ Optimization of the end plate to cage ratio is important since as this ratio decreases, the chance of graft subsidence increases as does the loss of lordosis.⁴⁶ With that said, their use in multilevel ACDF has been found to be successful clinically and to have maintained corrective lordosis.⁴⁷

Various graft options are available to the spine surgeon, including iliac crest autograft (often cited as the gold standard), corticocancellous allograft, PEEK cages, tantalum, and ceramic. A comparative study looking at iliac crest autograft alone, autograft with plate, and PEEK with plate found better maintenance of sagittal correction with plating, and no difference was seen between the PEEK and autograft plated groups.⁴⁸ This suggests that harvesting

iliac crest can be avoided without compromising sagittal alignment, and plate fixation is recommended. Initial stability is comparable among autograft, cancellous allograft, and fibular allograft.⁴⁹ Tantalum stand-alone interbody compared to autograft and plating was shown in a prospective randomized trial to have equivalent radiographic and clinical outcomes, including sagittal alignment.⁵⁰ Polyetheretherketone cages in stand-alone constructs have shown adequate fusion rates, but subsidence was seen.⁵¹ The amount of subsidence was significant compared to the immediate postoperative images, but was still acceptable according to the authors of the paper.⁵¹ Overall, bioceramics as grafts have yielded slower rates of fusion, and they must be used judiciously.^{52,53}

Posterior Cervical Fixation

Posterior subaxial cervical spine fixation is usually in the form of lateral mass screws with rods. Cervical pedicle screw placement is potentially more dangerous and certainly more difficult than lateral mass screw placement. The pedicle is bounded by nerve roots on its cephalad and caudal borders and the spinal cord medially. The vertebral artery sits in the foramen transversarium anterolaterally. A cadaveric study, where direct visualization of the pedicles was possible, still found violation of the pedicle with the screw 13% ($n = 7$) of the time.⁵⁴ In this study, the breach occurred laterally into the foramen transversarium six out of seven times, highlighting the potential complications with placement of pedicle screws in the subaxial cervical spine above C7.⁵⁴ Additionally, the morphology of the pedicles varied, requiring appropriate preoperative planning and negating a standardized approach for screw placement.⁵⁴

Biomechanically, lateral mass screws are inferior to pedicle screw placement. Pedicle screws have higher pull-out strength, lower rate of loosening, and different modes of failure compared to lateral mass screws.⁵⁵ Pedicle screws fail by fracture of the pedicle 40% of the time, suggesting that the fixation is strong enough that the bone fails before the screw-bone interface, while lateral mass screws pull out 90% of the time. Furthermore, maximum insertion torque correlated with failure of both screws, with the maximum torque of pedicle screws more than twice that of lateral mass screws.⁵⁵ The difference between the strength of lateral mass screws and pedicle screws relates to improved bone purchase with longer screws (more threads) and to purchase of stronger bone in the cortical walls of the pedicle.

Two common techniques exist for insertion of lateral mass screws: Magerl and Roy-Camille. The Roy-Camille technique utilizes a central start point in the lateral mass and aims 10° laterally and perpendicular to the posterior cortex. The Magerl technique employs a start point 1 mm cephalad and medial to the center of the quadrilateral surface of the lateral mass and aims 25° laterally and parallel to the facet joint in the sagittal plane. Barrey et al. compared the biomechanics of the two insertion techniques and found a small (~35N) but statistically higher pullout strength with the Roy-Camille technique, though this may in part be due to the testing environment.⁵⁶ Bicortical fixation was used in both techniques, and the thickness of the anterior cortex purchase was 20% higher (1.2 mm) in the Roy-Camille technique compared to the Magerl (1.0 mm). The Roy-Camille technique relies on screw purchase at the junction of the lateral mass and transverse process, whereas the Magerl technique relies on purchase in the anterosuperolateral corner of the lateral mass. Stronger purchase was also supported by the mode of failure, as the Magerl screws failed by pullout, whereas the Roy-Camille screws failed by lateral mass fracture.⁵⁶ With modern fixed-angled screw/rod constructs, unicortical screws are more commonly placed, and the longer Magerl screws may now perform better.

Cervical Disc Arthroplasty

Cervical disc arthroplasty (CDA) has developed as an alternative to fusion following anterior cervical discectomy in hopes that maintaining motion at the index level will minimize the development of symptomatic adjacent segment pathology. It has been shown that following placement of a CDA, postoperative overall cervical spine range of motion and motion at the functional spinal unit closely correlate to normal cervical motion in the lab and to preoperative motion in vivo.^{57,58} Bauman et al. in a recent biomechanical study comparing intact spines to those implanted with CDA also showed that CDA maintained motion without altering the contact pressures of the facet joints at the index level.⁵⁹ The authors noted that smaller implants were utilized to avoid “overstuffing” the disc space and to allow improved motion. This is an important technical point to consider when placing the CDA, which may otherwise lead to loss of motion and accelerated degeneration. Design characteristics also affect the loads on the uncovertebral and facet joints. Unconstrained and semiconstrained prostheses allow more load to be shared

by the native joints, increasing their stress, but Kang et al. note that this may prevent disuse osteopenia and subsequent degeneration of joint tissue.⁶⁰ Also important is the method of fixation. Implants with screw fixation may be more stable initially than keeled or toothed implants, while those with serrated edges exhibit the lowest strength for initial fixation.⁶¹

As has been stated, the often cited advantage of CDA over fusion is the preservation of normal motion and load at adjacent motion segments. Finn et al. in a cadaveric study showed that CDA was similar to the intact spine in flexion/extension and slightly less in lateral bending and axial rotation, consistent with implant design.⁵⁷ They also demonstrated increased strain at the adjacent segments in the fusion group compared to the CDA group, and it was postulated that this could contribute to degeneration and ultimately adjacent segment pathology.⁵⁷ Translational motions have also been shown to increase at levels above a fusion compared to CDA.^{62,63} This may also lead to abnormal stress on the joints and disc, accelerating degeneration.

Documentation of differences in adjacent segment pathology in the in vivo setting is less convincing to date. Kelly et al. in a prospective randomized trial with 2 years' follow-up found increased adjacent segment range of motion in the ACDF group, but not in the CDA group.⁶⁴ However, no difference was seen comparing ACDF to CDA.⁶⁴ Coric et al. in a prospective randomized trial with an average follow-up of 6 years (minimum 4 years) showed no difference in adjacent segment disease or reoperations.⁶⁵ They showed good clinical results in both groups with no difference in neck disability index (NDI) or visual analog scale (VAS) scores.⁶⁵ Garrido et al. with a 4-year follow-up comparing CDA to ACDF found more reoperations in the ACDF group for adjacent segment pathology, though not a statistically significant difference.⁶⁶ Presently, more studies with long-term data are needed to identify differences in adjacent segment pathology between ACDF and CDA.

In summary, a CDA following anterior cervical discectomy allows for more normal motion at the index level and at adjacent levels as compared to fusion. This has been shown in vitro as well as in vivo. It may decrease symptomatic adjacent segment degeneration, but this has not yet been confirmed clinically.

THORACOLUMBAR FIXATION

Most commonly, thoracolumbar fixation is achieved with pedicle screw fixation. Crossing the lumbosacral junction

may require pelvic fixation in addition. Interbody cages may be added for further stabilization.

Pedicle Screw Fixation

Thoracolumbar fixation has evolved from Harrington rod instrumentation to Luque wire and rod or hook and rod constructs to pedicle screw and rod constructs. Pedicle screws provide rigid three-column control and fixation with higher pullout strength compared to pedicle and laminar hooks.⁶⁷ Two prominent trajectories for pedicle screw placement are the straightforward (paralleling the vertebral end plate) and the anatomic (along the true anatomic axis of the pedicle) techniques.⁶⁸ Lehman et al. found maximum insertional torque and pullout strength using the straightforward technique.⁶⁸ In salvage situations, they also found that adequate fixation is offered by the anatomic technique when the straightforward technique fails.⁶⁹ The classic "in-out-in" placement of a pedicle screw has been assessed and compared to the straightforward technique, and similar pullout strength was found in a cadaveric study.⁷⁰

Insertion technique appears important as Paik et al. found that hubbing pedicle screws, where the base of the broad tulip portion of the screw is seated firmly against the bone at insertion, actually results in lower pullout strength compared to normally inserted screws.⁷¹ Computer tomography analysis of hubbed screws demonstrated a propensity for iatrogenic fracture development and is likely the reason for decreased strength.⁷¹ While some studies suggest that pedicle screws with a tapered minor diameter can retain pullout strength after backing them out, the study by Lill et al. clearly shows a loss of stability after back out.⁷² If tapered screws are utilized, they should not be backed out to avoid loss of fixation. Various screw designs are offered for fixation. Kim et al. investigated nine different screw designs in a biomechanical analysis and found that outer cylindrical and inner conical or tapered configuration offered the highest pullout strength regardless of the bone density.⁷³

Construct strength is imperative when arthrodesis is the surgical goal. In looking at short segment fixation, Jones et al. investigated the difference between all pedicle screw constructs and screw/hook constructs (Figs. 4.4A and B).⁷⁴ They found that all pedicle screw constructs were significantly stiffer and had higher pullout strength in a cadaveric model investigating the acute strength of a construct.⁷⁴

Figs. 4.4A and B: Short-segment construct utilized for stabilization and correction of (A) burst fracture; and (B) flexion-distraction injury.

The strength and control that the construct offers are even more important when performing spinal deformity correction. Kim et al. found that pedicle screw constructs offer better correction and improved pulmonary function postoperatively compared to both hook-only constructs and hybrid constructs,^{75,76} though at an increased cost.

Overall, pedicle screw fixation provides improved spinal fixation, stiffness, and pullout strength compared to wire and hook constructs. The straightforward technique offers better biomechanical strength compared to the anatomic technique, and the spine surgeon should be cautioned regarding hubbing the screw as this weakens bone purchase.

Sacral and Pelvic Fixation

Sacral fixation is important in stabilizing the caudal portion of the construct. Lehman et al. compared bicortical S1 screws to tricortical S1 screws placed in the sacral promontory.⁷⁷ They found that placing screws into the sacral promontory significantly increased insertion torque.⁷⁷ In salvage situations, S2 alar screws can safely be placed and have yielded comparable radiographic results.⁷⁸

Fixation to the pelvis is important in deformity constructs where a long moment arm is created and control is needed to maintain the correction. Options include Galveston rods, iliac bolts and screws, and sacral alar iliac fixation (Figs. 4.5A and B).⁷⁹ Peelle et al. showed that iliac screws provided equivalent maintenance of pelvic

obliquity and scoliosis correction as Galveston rods, but with less implant complications and without the need for complex three-dimensional bending of the rods.⁸⁰ Tis et al. investigated the strength of constructs with or without fixation to the pelvis and with or without sacral screws.⁸¹ They found that including fixation to S1 provided significant improved stability as well as the addition of iliac screws.⁸¹ Lebowhl et al. found that adding iliac fixation to S1 screw fixation decreased the strain on the S1 screw in axial compression and increased the load to failure versus adding only S2 screws.⁸² Clinically, Tsuchiya et al. showed that iliac screw placement in deformity surgery or in high-grade spondylolisthesis protected S1 screws from failing.⁸³ Furthermore, they did not find any evidence of sacroiliac degeneration with at least 5 years of follow-up.⁸³ Santos et al. found that trajectory of the iliac screw to either the anterior superior iliac spine (ASIS) or the supra-acetabular location did not matter, but 9.5-mm screws had greater torque than 7.5-mm screws.⁸⁴ Screws inserted to >80 mm also had improved insertion torque.⁸⁴ Fixation down to S2 instead, utilizing iliac bolts, has been shown biomechanically to have comparable stiffness, but insertion torque is significantly less and may be the reason to prefer iliac bolt usage.⁸⁵

Recently, Chang et al. have reported on a modified technique for iliac fixation with the starting point in S2 as an alternative to the iliac starting point.^{79,86} The initial clinical reports of this technique are encouraging (Fig. 4.5B), but biomechanical testing has not been completed to date.

Figs. 4.5A and B: Fixation to the pelvis in deformity cases provides added stability compared to ending with S1 pedicle screws. (A) Iliac bolt placed with posterior superior iliac spine (PSIS) as starting point. (B) S2-ilium bolt placed with starting point just caudal to S1 neuroforamen.

In summary, sacral fixation with S1 pedicle screws into the sacral promontory is ideal, and fixation to the pelvis with iliac screws is biomechanically superior and recommended in deformity cases.

Vertebral Interbody Cages

Spine surgeons use interbody cages in the lumbar spine to increase stability and fusion rate, and sometimes to improve spinal alignment. Surgical approaches include anterior [anterior lumbar interbody fusion (ALIF)], posterior [transforaminal lumbar interbody fusion (TLIF)], posterior lumbar interbody fusion (PLIF), and lateral. From an approach standpoint, Ploumis et al. found comparable stability between TLIF and ALIF done from lateral or direct anterior approach when posterior pedicle screw fixation was used.⁸⁷ Whether an ALIF needs posterior augmentation has been addressed in a recent biomechanical study that showed anterior plating provided significant restriction to range of motion under physiologic load and improved stiffness, though pedicle screw fixation did provide further enhancement to stability.⁸⁸ It does appear that interbody cage placement is markedly benefited by supplemental fixation with anterior plate fixation or posterior pedicle screw placement.⁸⁹ When considering pedicle screw fixation, bilateral screw fixation seems to provide better restoration of segmental stability following TLIF.^{90,91}

Lateral approach interbody fusion has recently gained popularity as new techniques for neurologic monitoring

have allowed a transposas approach. Lateral interbody fusion allows for preservation of the anterior longitudinal ligament while providing access for near-complete disc removal, end plate preparation, and large interbody spacer placement.⁹² This has shown to provide significantly increased immediate stability, even as a stand-alone device. Stabilizing these constructs with bilateral pedicle screws is often recommended as well.⁹²

The use of expandable interbody cages is intriguing in tumor, infection, and traumatic reconstructions as well as in deformity (Figs. 4.6A and B). Expandable cages for PLIF with pedicle screw fixation have been shown to aid in restoring lordosis and create a stable construct.⁹³ These have also been used for TLIF (Fig. 4.7). In a corpectomy model, expandable cages did not provide adequate stability even with anterior plating, and the authors' recommendations were to avoid use as a stand-alone implant.⁹⁴ One significant concern with the use of expandable cages is the potential for subsidence with the increased end plate loading when deploying the cage and subsequent end plate fracture.⁹⁵ Clinically, this has been less of a concern, as noted in a large study on tumor reconstructions where good durability of an expandable titanium cage was noted in 95 patients, with excellent maintenance of lordosis and only minimal subsidence that did not require revision surgery.⁹⁶ Overall, expandable cages have a positive clinical history, especially when augmented with pedicle screw fixation.

Figs. 4.6A and B: Anteroposterior and lateral views of expandable vertebral reconstruction cage filled with allograft placed for infection following corpectomy. Note angled footplate to aid in restoration of lordosis.

Fig. 4.7: Expandable interbody cage placed that increases in size after implantation. It provides increased lordosis as part of sagittal balance correction.

Cross-connectors, also known as cross-links, may be a useful adjunct to the stability of a construct.⁹⁷ This is particularly important when screws are not placed at every level and in deformity cases with long constructs where axial rotation needs to be better stabilized.⁹⁸ They may also help in short-segment trauma constructs to enhance stiffness.⁹⁹

FIXATION IN THE OSTEOPOROTIC SPINE

The aging population presents a problem for the spine surgeon with the increasing rate of osteoporosis. Attempt-

ing fixation in the osteoporotic spine presents its own challenges. Numerous techniques and technologies have been employed to combat the difficulties of poor fixation. Biomechanical testing has shown that expandable screws have higher ultimate loads and energy to failure compared to standard screws.¹⁰⁰ Cement augmentation of pedicle screws using fenestrated screws has become a popular alternative. Choma et al. found that cannulated fenestrated screws with cement augmentation provided significantly more resistance to pullout compared to both solid screws with cement augmentation.¹⁰¹ The use of fenestrated screws allows for safe placement of the cement into the vertebral body and not into the canal.¹⁰¹ Pare et al. supported these findings and also found that with extraction of the screws the cement sheared off at the fenestrations, facilitating safe removal.¹⁰²

DYNAMIC STABILIZATION

Interspinous process devices/spacers have gained recent attention as less invasive methods of providing an indirect decompression for patients with lumbar spinal stenosis. Wan et al. demonstrated that an implanted interspinous device significantly increased the intervertebral foraminal area and segmental canal length at the surgical level without effects on the adjacent levels.¹⁰³ This same group also showed that an interspinous device effectively increased the interspinous process distance at the index level during several motions of the spine without increasing the interspinous process distance at the adjacent levels.¹⁰⁴

These devices are predominantly used in elderly patients, and long-term data are still needed to assess the concern for recurrent symptoms with implant displacement, subsidence, or spinous process fracture.

Lumbar disc arthroplasty remains a popular area of interest by patients and surgeons for treatment of discogenic back pain. Maintaining motion at the spinal segment after removing the disc to eliminate the potential pain generator is a biomechanically attractive option. Demetropoulos et al. demonstrated in cadaveric models that disc arthroplasty prevents the additive stress on adjacent levels occurring with fusion, while maintaining motion, though slightly less than the intact spine.¹⁰⁵ Auerback et al. additionally found that not only do forces increase at adjacent levels, but sagittal plane translation also occurs after fusion.¹⁰⁶ Gao et al. demonstrated that adjacent-level intradiscal and facet joint pressures remain near intact values, while fusion significantly increases forces on these structures.¹⁰⁷ This would presumably decrease the incidence of symptomatic adjacent segment pathology. However, the decreased load has been questioned in a study by Botolin et al.,¹⁰⁸ and clinical studies have not confirmed the change in symptomatic adjacent segment pathology. Overall, disc arthroplasty in the lumbar spine is a field that continues to advance, and more studies are needed to see long-term outcomes and effects on adjacent segments and motion preservation.

The use of dynamic pedicle screw fixation to provide stability without rigid fixation and fusion has gained some limited popularity, though it may not perform as hoped.^{109,110} Wu et al. raised the significant concern for screw loosening and found it in 20% of patients at 3-year follow-up.¹¹¹ Yu et al. have investigated combining dynamic pedicle screw fixation with TLIF in a cadaveric model to allow increased graph loading. They were able to demonstrate increased stability while facilitating loading of the graph to potentially improved fusion rates.¹¹² This requires further study with clinical assessment to support the fusion claims and clinical use.

Facet joint arthroplasty is currently being investigated as a surgical treatment for spinal restabilization after facetectomy for lumbar decompression. Phillips et al. showed that after laminectomy and complete facetectomy, facet arthroplasty restored motion at the index level as well as at adjacent levels in a cadaveric model.¹¹³ However, it remains to be seen if these systems can withstand physiologic loads over time. Sjoqvold et al. demonstrated varying moments and bone-implant loads depending on the motion intro-

duced to the spine.¹¹⁴ Rigid fixation demonstrated different loads compared to facet arthroplasty, and therefore further clinical trials are needed to determine their longevity.¹¹⁴

Dynamic stabilization constructs continue to evolve, and long-term data are needed to see if motion can be maintained without effects on adjacent motion segments.

KEY POINTS

- Occipital plate and screw/rod constructs are stronger than wire/rod constructs, and screws placed midline in the occiput are stronger than laterally placed screws. Lateral screws provide more control in lateral bending.
- When stabilizing the atlantoaxial motion segment, posterior fixation with either C1/2 transarticular screws or C1 lateral mass/C2 pedicle screw constructs is significantly stronger than wire constructs. Translaminar screws in C2 provide adequate fixation in salvage situations.
- Anterior dynamic cervical plating allows controlled settling to maintain load on the graft and facilitate faster fusion rates with fewer plate complications.
- Thoracic pedicle screw constructs are stronger than hook and wire constructs.
- Interbody cage placement provides a load-sharing environment and reduces strain on pedicle screw constructs.

- » Waddell's Signs

INTRODUCTION

Accurate diagnosis of spinal pathology must include a complete and thorough physical evaluation. Commonly, nerve root compression will result in radicular symptoms while spinal cord compression will result in myelopathic symptoms. The physical examination findings, including provocative maneuvers, will establish a baseline neurologic status that guides the differential diagnosis ultimately drives treatment options.

GENERAL EVALUATION

Observation

Casual observation of the patient throughout the encounter can provide valuable information. It is important to pay attention to the patient's overall behavior to observe their functional activity and to identify any signs of pain such as wincing or limping. This type of inspection is most useful when the patient is unaware that they are being observed.¹ Watch for any signs of frustration or depressed mood since these can be indicators of chronic pain or functional limitations.

More specific observation begins with assessing the patient's overall alignment, so it is important to note their posture, including any signs of torticollis, kyphosis, or

scoliosis. Ask the patient to remove all garments except underwear and to put on a gown that opens in the back to allow proper inspection of the neck, spine, pelvis, and lower extremities. Stand to the side to look for cervical and lumbar lordosis as well as for thoracic kyphosis and then move behind to view the coronal alignment of the spinal column as well as the shoulders and iliac crests.

Alignment of the head with respect to the center of the pelvis, shoulder heights, and pelvic tilt are important indicators of truncal shift.² Observe whether these findings are fixed or if they change with position. Note any other abnormalities such as prior surgical incisions, asymmetries, erythema suggesting underlying infection, muscular atrophy, abnormal pigmentation, possible indicators of neurofibromatosis such as skin tags or café-au-lait spots, or any signs of trauma (ecchymosis, lacerations, and scars). Webbing of the neck suggests underlying congenital anomaly.

While the patient walks around the room, observe their gait pattern to see if there is any impairment or rigidity and then watch them doing routine tasks such as removing their shoes to see if these can be done without difficulty. Difficulty initiating muscle activity such as that seen when rising out of a chair or starting to walk may reflect basal ganglia pathology such as Parkinson's disease. Certain gait patterns such as a spastic and scissored gait can indicate upper motor neuron pathology including potential spinal

Fig. 5.1: Regional nervous sensory distribution as illustrated in a dermatome map.

cord compression, injury, or tumor. An antalgic or shortened stance phase gait indicates ipsilateral lower extremity musculoskeletal pathology. Suspicion of hip, knee, or foot pathology can be confirmed with focused examination of those areas. Tandem (heel-to-toe in a straight line) gait analysis may assist in exposing previously unseen ataxia. Observing gait abnormalities and posture may lead to a better understanding of pain patterns as well as underlying neurologic dysfunction. Such observations may also help to identify extraspinal conditions affecting gait such as intrapelvic pathology (leg length discrepancy, lower extremity contractures) as well as intrapelvic conditions, typically related to prior trauma.

Palpation

Ask the patient to stand in front of you, and palpate each spinous process with your thumb. Tenderness localized to specific spinous process could be a sign of fracture, dislocation, arthritis, or infection. Tenderness between the spinous processes suggests soft tissue injury. Any unusual prominence or recession of a spinous process should be noted, especially in the lumbar region, since these step-offs suggest spondylolisthesis.³ Palpate the facet joints in the cervical region; these are located deep to the trapezius so they may be difficult to appreciate. The nuchal ridge at

4	Motion against gravity and mild resistance
5	Motion against full resistance

the posterior occiput is often tender in paraspinal sprain and occipital neuralgia.⁴ Feel for masses and tumors in the bony and soft tissue regions that may be present as well.

Sensation

Dermatomal distribution of symptoms helps to localize the pathology to specific nerve roots or to specific peripheral nerves. Spinal nerve root dermatomes are illustrated in Figure 5.1. Sensation can be tested through the use of pinprick, light touch, light and deep pressure, vibration, temperature, and pain. Dermatomes corresponding to compressed nerve roots have significantly more sensory dysfunction than unaffected nerve roots on the contralateral side.^{5,6} However, sensory testing alone may only localize dysfunctional nerve roots half of the time.

Motor Testing Grades

Motor testing allows muscles to be graded on a scale from 0 to 5 (Table 5.1).⁷ Strength impairment on physical examination has been shown to correlate with high likelihood of associated anatomical abnormalities on magnetic resonance imaging (MRI), with a predictive odds ratio of 5.2.⁸ Specific muscular testing will be discussed in subsequent sections.

Reflexes

Before testing for deep tendon reflexes, make sure that patient is fully relaxed. Reinforcement activities can help with this since they engage other muscles while the patient relaxes the muscles of interest. For example, when testing the knee jerk reflex, ask patients having difficulty relaxing to clasp their hands together and pull apart until reflex testing is completed. Always evaluate for any asymmetry between the sides.

Reflexes are graded from absent (0) to hyperactive (4+) as seen in Table 5.2.⁷ These relative values should be

Table 5.2: Reflex response grading.

0	No response
1+	Minimal response
2+	Normal response
3+	Slightly increased response
4+	Hyperactive response, clonus

assigned keeping patient's age in perspective since "normal" reflex response may deteriorate with age. Hyperreflexia and/or clonus suggests involvement of upper motor neurons. Hyporeflexia could indicate damage to the nerve roots, peripheral nerves, neuromuscular junctions, or muscles themselves. However, hyporeflexia is more commonly the natural consequence of aging and degeneration.

Range of Motion

First attempt passive movements, and then ask the patients to perform active motions on their own. Note the differences in range of motion between passive and active motion, and verify if pain is elicited with both passive and active motion. Range of motion asymmetry due to pain rather than stiffness typically raises more suspicion of spinal pathology.

CERVICAL SPINE EVALUATION

Gait

Gait analysis can reliably indicate progression in individuals with cervical spondylotic myelopathy (CSM).⁹ Patients with a wide-based gait may have cerebellar pathology or CSM.¹⁰ Smooth, continuous gait can be disrupted with CSM because this condition may lead to spasticity with resulting loss of the hip and knee range of motion needed for a fluid gait. Gait trials can be performed in the room or with short walking tests to evaluate gait speed, stride length, and amount of time spent in stance versus swing phases.^{11,12}

Range of Motion

It is important to only examine range of motion on patients whose cervical spine has been cleared from bony or ligamentous injury. If there is a history of trauma, perform the movements carefully in order to not exacerbate any residual injury. Have the patient sit or stand upright with proper posture, shoulders relaxed, and arms by the side.

Between tests, allow the patient to recover to a neutral cervical position. As a further test, have the patient perform each range of motion maneuver again, but this time against gentle, steady resistance provided by the palm of your hand.¹³

Flexion/Extension

Stand slightly behind and at the patient's side, place one arm behind their neck, and hold their far shoulder to ensure they are only bending their neck while the thoracic and lumbar spines remain neutral. Ask them to slightly open their mouth and relax their jaw to minimize tension on the platysma.

Place two fingers on the back of the patient's head. Passive flexion is then tested by gently pushing their neck forward until tenderness or stiffness is elicited or until the chin touches the manubrium. Allow the patient to return to neutral position and then evaluate active flexion by asking them to repeat the motion without assistance to see if they can touch their chin to their chest to test the firing of the sternocleidomastoid muscle. Passive extension can be tested by placing two fingers on their forehead and slowly pushing their neck into extension, moving the head backward as far as tolerable. Active extension and function of the primary extensors (trapezius, capitis, semispinalis, and splenius) are then checked by asking the patient to repeat these motions as far as possible.¹³

Approximately 50% of cervical flexion/extension comes from the occiput–C1 junction while roughly 50% of cervical axial rotation comes from the C1–2 junction. Most patients can nearly touch their chin to their chest in flexion and it is useful to document (measuring in centimeters or in fingerbreadths) the distance of the chin from the chest in flexion and the occiput from the dorsal spine in extension.

Lateral Bending

Stand behind the patient. Place your left hand on the patient's left shoulder for stability, ensuring that the patient is not shifting their shoulders or distal spine or rotating their neck. Cup the right side of their head in your right palm and gently bend the neck toward the left shoulder. Then ask the patient to bring the left ear to the ipsilateral shoulder. Repeat the passive and active movement to the opposite side. These movements rely on action of the scalene muscles. Nearly 45° of motion in either direction is common.

Rotation

Stand behind the patient and have them face away from you. Place one hand on the patient's forehead, and cup the back of their head with your other hand. Allow your elbow to gently rest on the patient's shoulder to confirm that only the neck, not the trunk, is rotating. Next, assess the sternocleidomastoid by instructing the patients to turn their head as far as possible to each side. Many patients can rotate 75–90° in either direction. Any asymmetry should be noted. If pain is elicited with rotation, perform the rotation while the neck is in flexion to unload the facet joints. Then, repeat the motion while in extension to load the facet joints.

Palpation

Allow the patient to lie prone on the examination table, or have them sit while you stand behind them. Palpate the spinous processes of the cervical spine. The most superior palpable process is usually that of C2 and the most prominent spinous process is C7. An alternative examination method is to use your second and third digits to appreciate the spinous processes in the posterior neck while holding your thumb anteriorly on the midline with the patient supine. Note any sites of spinous process tenderness, paraspinal tenderness associated with spasm of paravertebral muscles, or any malalignment, particularly in the setting of trauma. Paracervical muscle tenderness and spasm is more common than spinous process tenderness, but it is nonspecific. Palpate the facet joints that lie deep to the trapezius muscle, so ask the patient to keep the neck muscles tension free for optimal facet examination. Also feel the trapezius muscle and the nuchal ligament, which traverses from the C7 spinous process to the inion at the base of the posterior skull. Pain at the scapular spine trapezius insertion or at the nuchal ligament may indicate possible whiplash injury from flexion and extension injury.¹³ For patients with upper cervical/occipital symptoms, palpate several centimeters lateral from the midline at the base of the occiput in the area of the greater occipital nerve.

Palpate the sternocleidomastoid muscle as it traverses from the mastoid to the clavicle. If patients are able, have them laterally extend their head against resistance while rotating their neck contralaterally. This defines the action of the sternocleidomastoid muscle. Carotid pulses can be palpated immediately lateral to first cricoid ring, but must be palpated individually to avoid simultaneous bilateral

blood flow occlusion. Next palpate the lymph nodes along the medial edge of the sternocleidomastoid muscle, which may be prominent with infection, malignancy, or other inflammatory pathology. Gently palpate the hyoid bone (near level of C3), the thyroid cartilage (near level of C4/C5), the cricoid (near C5–6), and the thyroid gland. Next, with the patient supine, examine the supraclavicular fossa as well for enlarged lymph nodes.

Sensation

Begin the sensory examination of the cervical spine by palpating the region around the thyroid cartilage, which has sensory innervations from the second cervical nerve root. The distribution of the C3 nerve root is inferior and anterior, or on the posterior-lateral aspect of the neck to the mastoid and the pinna of the ear. C4 sensory innervation extends from medial to the glenohumeral joint anteriorly to the chest as well as posteriorly to the superior scapula. C5 dermatomal extensions of the axillary nerve are more lateral and distal, including the lateral arm to the elbow. C6 innervates dorsal thumb and index finger sensation as well as to the lateral forearm that is peripherally innervated by the musculocutaneous nerve. C7 innervates the mid-dorsal forearm down to the middle finger dorsally while C8 innervates the medial forearm and T1 the medial upper arm. Pathology of C8 and T1 nerve roots can be confused with lesions of the more peripheral medial antebrachial branch of the cutaneous nerve. Sensory innervation areas are summarized in Figure 5.1 as well as Table 5.3.

Motor

The motor examination entails testing of specific muscles, deficiencies of which may correlate with various pathologies including nerve root impairment (Table 5.3). Extremities can be tested individually or simultaneously to allow for comparison between the sides.⁷

C5–C6

The deltoid and biceps are innervated primarily by C5 with assistance from C6; wrist extensors are innervated primarily by C6 with assistance from C5. To test these myotomes, begin with assessment of the deltoid muscle through shoulder abduction. Help the patient abduct the shoulder to 30° and then ask them to abduct further. Place one hand on the patient's hip to aid in trunk stabilization, and apply gentle resistance with the other hand. Next, evaluate

Table 5.3: A summary of cervical neurology.

<i>Disc</i>	<i>Root</i>	<i>Sensation</i>	<i>Muscle</i>	<i>Reflex</i>
C2-3	C3	Distal neck	Sternocleidomastoid, longus colli, rectus capitis	
C3-4	C4	Medial arm	Trapezius, splenius capitis	
C4-5	C5	Lateral arm	Deltoid, biceps	Biceps reflex
C5-6	C6	Lateral forearm	Biceps, wrist extension	Brachioradialis reflex
C6-7	C7	Middle finger	Triceps wrist flexors, finger extensors	Triceps reflex
C7-T1	C8	Medial forearm	Finger flexors hand intrinsics	
T1-T2	T1	Medial arm	Hand intrinsics	

bicep function by standing in front of the patient. Flex the patient's elbow to 90° and place one hand below the elbow and the other around the wrist to prevent forearm pronation. Ask the patient to flex in supination as you resist. Next, hold patient's forearm and ask them to extend the wrist as your other hand resists their force.

C7–C8

C7 assessment can be performed through triceps and common finger extensor testing as well as by evaluation of wrist flexion, with flexor carpi radialis and flexor carpi ulnaris receiving innervations from C7 and C8. Position as you did to evaluate wrist extension, but this time ask the patient to flex against your resistance to test the wrist flexors. Then grasp the patient's elbow with one hand and grab their ipsilateral wrist with the other. Ask them to extend their elbow and provide resistance in order to evaluate triceps strength.

C8–T1

Finger abduction and adduction, as well as finger flexion, can be performed to assess the integrity of the C8 and T1 nerve roots. Dorsal and palmar interossei are responsible for finger abduction and adduction, respectively. Ask the patient to first abduct and then adduct the fingers while you exert force in the opposing direction. You can also test the integrity of C8 and T1 through finger flexion assessment of the flexor digitorum profundus and flexor digitorum superficialis. Assess finger flexion next by having the patient clasp their fingers into a fist around your fingers and try to extend the patient's fingers if possible.

Reflexes

As previously noted, it is important for the patient to be fully relaxed during the reflex examination, so ensure that

their elbow and wrist joints are without tension. Stand in front of your patient and allow the patient's forearm to rest on your forearm of the same side. With your palm, gently hold the patient's elbow and place your thumb on the bicep tendon. With a soft, smooth motion, strike your thumb; watch for bicep contraction, and simultaneously feel for the contraction of the tendon below your thumb. If either of these occurs, the C5 reflex is intact.

The brachioradialis reflex tests the C6 nerve root. Hold the patient's forearm with your contralateral hand and ask the patient to let the wrist hang down without tension. Gently tap the brachioradialis tendon to elicit a response.

The triceps reflex assesses the C7 nerve root. Place your hand proximal to the antecubital fossa and allow the patient's elbow to hang loosely so that fingertips are pointing downward. Tap the triceps tendon with a reflex hammer proximal to the olecranon.

All three normal upper extremity reflexes are outlined in Table 5.3.

Biceps hyperreflexia has been shown to be the most sensitive for detecting myelopathy (62%), but with only 49% specificity. The triceps and brachioradialis reflexes are both more specific (78% and 89%, respectively) and less sensitive (36% and 21%, respectively).¹⁴

Provocative Testing

Cervical radiculopathy can originate from a herniated disc, foraminal stenosis, spondylosis, or any other pathology such as malignancy or infection that leads to nerve root compression. A number of provocative maneuvers are useful to assess compressive pathology.

Spurling's Test

Spurling's test, as originally described, is performed by placing axial compression on the head while rotating the

Fig. 5.2: The Spurling's test—neck extension, lateral bending, and axial loading recreates the arm pain in a patient with cervical radiculopathy due to decreased neuroforamen diameter and thus increased nerve root impingement.

neck axially and flexing it laterally to the ipsilateral side of the symptoms (Fig. 5.2).¹⁵ The test is considered positive if the radicular pain or symptoms are reproduced with the maneuver, presumably because it further decreases foraminal diameter and increases nerve root compression. Later studies have noted that adding cervical extension to the maneuver results in a higher incidence of recreating patient symptoms.¹⁶⁻¹⁸ The ranges for sensitivity and for

specificity using this maneuver for cervical radiculopathy are 30–90% and 92–100%, respectively.^{17,19,20}

Valsalva Maneuver

The Valsalva maneuver is performed by having the patient forcibly exhale against a closed airway. If pain or radicular symptoms are reproduced, a compressive lesion may lie within the spinal canal.²¹ This maneuver has low sensitivity (22%), but high specificity (94%).²² One study evaluating autonomic function in patients with cervical myelopathy noted a significant impairment of the autonomic response to the Valsalva maneuver when compared to controls.²³ As described later, this maneuver is also used to diagnose lumbar disc herniation.²⁴

Arm Abduction Relief Sign

Patients presenting with radicular pain sometimes find that their pain is decreased when they “hold their hand behind their neck.” This position—where the shoulder is held in abduction with elbow flexion²⁵—is believed to decrease tension on the exiting cervical nerve root, as demonstrated in Figures 5.3A and B. Abduction relieves the pressure on the exiting nerve root from herniated disc material anterior and inferior to the vertebral interspace. As the arm is adducted, the nerve root is pulled inferiorly and is increasingly compressed by the disc, reproducing

Figs. 5.3A and B: Arm abduction sign—a patient with cervical radiculopathy will place their arm on their head to decrease tension on the nerve root being compressed proximally by a disc herniation. (A) A patient with a cervical disc herniation will have increased tension on a nerve root with the arm in adduction. (B) With the arm in abduction, the nerve root is moved away from the herniated disc and thus there is less tension on the nerve root.

Fig. 5.4: Brachial compression test—compression of the brachial plexus by the physician's thumb will increase tension on the nerve root being compressed proximally by a disc herniation.

symptoms. No such relief will be found with stenosis as the nerve root impingement is fixed. The sensitivity of this arm-abduction sign was found to range from 17% to 78%,^{26,27} while specificity has been found to be 80–100%.^{19,28}

The arm-abduction sign may be used to differentiate between cervical radiculopathy caused by a herniated disc and foraminal stenosis.²⁹ It may also be used to differentiate shoulder pathology from cervical pathology. Shoulder abduction may also be used in conjunction with conservative management of cervical radiculopathy as a means to relieve symptoms.³⁰

Brachial Plexus Compression Test

Compression of the brachial plexus with the physician's thumb (Fig. 5.4) is likely to elicit localized pain in most asymptomatic individuals. However, in patients with MRI evidence of mechanical lesions of the cervical spine, this test may provoke radiating pain to the shoulder or upper extremity by increasing tension on a nerve root that is already under tension by a disc herniation. Sensitivity in this maneuver was 69%, with a high specificity of 83%.³¹

Myelopathy

Myelopathic symptoms result from upper motor neuron lesions or compression of the spinal cord, and may include gait instability, clumsiness or difficulty with upper extremity dexterity, and urinary dysfunction. Several maneuvers exist that can help assess a patient for signs

Fig. 5.5: Hoffman's sign—flicking the dorsal aspect of the middle fingernail between the examiner's thumb and index finger will cause thumb interphalangeal joint or index finger proximal interphalangeal joint or distal interphalangeal joint flexion in a patient with cord compression.

of cord compression. Pathologic findings include hyperreflexia, sustained clonus, an inverted brachioradialis reflex, or positive Babinski, Oppenheim, Hoffmann's sign, or finger escape signs. Although patients with cord signal changes on MRI are more likely to demonstrate myelopathic signs than controls, nearly 21% of myelopathic patients may not exhibit a single sign.¹⁴

Hoffmann's Sign

The Hoffmann's sign is performed by placing the patient's hand at rest and flicking the dorsal aspect of the middle fingernail between the examiner's thumb and index finger. This activates the extensor mechanism, and is considered positive if a resultant reflex contraction occurs in the thumb interphalangeal joint or index finger proximal interphalangeal joint or distal interphalangeal joint (Fig. 5.5). In a normal asymptomatic patient, no such contraction will occur. For cervical myelopathy, the Hoffmann's sign has been shown to have a sensitivity of 58–68% and a specificity of 78–84%.^{14,32,33} This finding may also be seen in asymptomatic individuals with underlying cervical cord impingement, although further imaging workup has not been shown to alter treatment plans in such patients.³⁴ A dynamic Hoffmann's sign has also been described wherein the maneuver is first performed with the head in neutral and then repeated after multiple active flexion-to-extension neck exercises. This may elicit a positive response in patients with early spondylotic myelopathy

Fig. 5.6: L'Hermite's sign—in a patient with cervical myelopathy, flexion of the neck causes increased compression of the cervical spinal cord and will create an electric shock sensation throughout the extremities.

Fig. 5.7: Finger escape sign—weakness of the intrinsic muscles leads to weaker adductors than abductors, and patients with myelopathy have difficulty with maintaining adduction of the ulnar fingers.

who may not yet have static cord compression, but whose narrowed spinal canal dynamically irritates the cord.³⁵

Inverted Radial Reflex

The inverted radial reflex (also known as inverted supinator reflex, and inverted brachioradialis reflex) is a sign of C5–C6 myelopathy and is considered positive if eliciting the brachioradialis reflex with the forearm in neutral rotation causes ipsilateral flexion of the fingers.³⁶ Sensitivity and specificity are 51%,¹⁴ and this reflex may be present in up to 25% of asymptomatic individuals.³⁶

L'Hermite's Sign

L'Hermite's sign is considered positive if flexing the cervical spine reproduces electric-like sensations into the extremities. More specifically, cervical pathology is suspected if this sign is elicited with neck flexion (Fig. 5.6) and thoracic pathology is suspected if it is elicited with trunk flexion.²¹ Low sensitivity and high specificity have been noted without exact percentages³¹ for this sign. Evidence-based evaluations of this sign for cervical pathology are lacking, but have been described for multiple sclerosis, tumors, spondylosis, and myelitis.²⁸

Fast Motor Testing

Fast motor testing may be used to assess the upper and the lower extremities for motor dysfunction due to cervical myelopathy. The *foot tapping* test may be used to analyze

the lower extremity. The patient is seated with both hips and knees at 90° of flexion, and with the heel resting on the floor the patient taps the sole of their foot as many times as possible in 10 seconds. Normal is 20 times in 10 seconds. Either test is positive if the patient cannot maintain their initial pace.

Similarly, the upper extremities can be assessed with the grip and release test. The patient fully flexes and extends their fingers as many times as possible during a 10-second interval. Normal is over 20 times in 10 seconds.

Both the foot tapping and grip and release test have been shown to have significant deficits in patients with myelopathy when compared to controls.^{37,38}

Finger Escape Sign

The patient is asked to hold their hand with all five digits adducted and extended for 30–40 seconds. The sign is positive for cervical myelopathy when the little finger is held in slight abduction at rest and cannot be actively adducted for >30 seconds, as shown in Figure 5.7.³⁸ As the myelopathy progresses, the ring finger is also weak in adduction, and in more advanced cases the interphalangeal joints become flexed and in severe cases the metacarpophalangeal joints are also fixed in flexion. The result is a patient who can only hold objects with the thumb and index finger.

Clonus

Clonus (rhythmic oscillation between flexion and extension) is typically examined at the ankle. With the patient

relaxed, the ankle is briskly dorsiflexed and maintained in a dorsiflexed position. While a few clonic beats may be normal, sustained beats (over three) are indicative of myelopathy. Sensitivity for detecting myelopathy was found to be only 13%, but with 100% specificity.¹⁴

Babinski Reflex

The Babinski or plantar response reflex is performed by stroking the lateral plantar aspect of the foot from the heel curving medially to the ball of the foot. A normal response is plantar flexion of all toes. A positive finding occurs with dorsiflexion of the big toe with fanning of the lateral toes and suggests upper motor neuron pathology.³⁹ Although it is not highly sensitive (13%), the reflex has been shown to have a specificity of 100%.¹⁴ Oppenheim's sign is closely related. This sign is positive when firm pressure applied along the crest of the tibia elicits a response similar to that seen in Babinski testing.

Additional Assessment

Care must be taken not to interpret upper extremity pain as radiculopathy when in reality it is due to primary musculoskeletal or peripheral nerve pathology. As such, a complete examination of the upper extremity should be performed as part of a comprehensive spinal evaluation.

Primary shoulder pathology may mimic cervical radiculopathy. The shoulder examination begins with general inspection. This should include evaluation of previous surgical scars, asymmetry, atrophy, arm position, and gross deformity. The muscles and bony anatomy should then be palpated with particular attention to underlying muscle tone and any tenderness. Examination of active and passive shoulder range of motion as well as rotator cuff strength is important to assess pathology such as rotator cuff tears, impingement, instability, or adhesive capsulitis.¹⁸ Patients may also present with dual disease of both the shoulder and cervical spine. Both conditions require appropriate management.⁴⁰

Radicular pain, paresthesias, and/or extremity weakness may not be due to cervical nerve root pathology and common compressive peripheral nerve pathologies such as carpal tunnel syndrome, cubital tunnel syndrome, and brachial plexopathy should remain in the differential diagnosis. Diagnosis can be made through careful history and physical examination of radial, ulnar, and median nerve function with isolated sensory examination and muscle strength testing. Specific provocative tests including

Tinel's sign at the elbow and wrist, and Phalen's maneuver at the wrist should be performed. Electrodiagnostic testing such as nerve conduction studies and electromyography can assist the physician with differentiating central versus peripheral nerve compression.⁴¹⁻⁴³

Suspicion of possible *thoracic outlet syndrome* can be assessed with the Adson test. In this maneuver, the affected arm is passively externally rotated and extended as the shoulder is abducted. The test is positive if the radial pulse is lost or if symptoms are exacerbated.

THORACIC SPINE EVALUATION

Observation

Evaluation of the thoracic spine begins with inspection of overall spine alignment in the coronal, sagittal, and axial planes. Note any deformity such as a gibbus or step-off. Check to see if the shoulders are levelled, if the pelvis is level, and if the skin folds on the trunk are levelled. Trunk balance can be estimated by hanging a weighted string from the region of C7; the weight should fall midway between the gluteal folds. Placing one hand under the patient's shoulder and another on the hip while applying gentle force may help assess curve rigidity. Have the patient bend forward letting their arms dangle in front of them above their toes to evaluate their sagittal plane. If there is a kyphosis, is it fixed or does it seem flexible? Is it a short, sharp deformity or it long and gentle? Note that forward bending may be limited by hamstring tightness such as that seen with spondylolisthesis.

Sensation

Localization of spinal cord pathology in the thoracic region relies heavily on dermatomal analysis as outlined in Figure 5.1. Reflex testing is generally of minimal use in this region since muscles innervated by thoracic nerve roots have mixed innervations. Thus, either muscle or reflex deficiencies may suggest spinal pathology, but do not help in pinpointing the specific site of the pathology.

Scoliosis Assessment

Adam's Forward Bending Test

The Adam's forward bending test is a simple maneuver to screen for thoracic or lumbar scoliosis.⁴⁴ This evaluation brings out axial spinal rotation and is performed by asking the patient to lean forward and reach with their fingers

toward their toes; a direct measurement or a scoliometer is used to measure the angle or height of prominence of one side as compared to the other. This test can also be used in the lumbar spine in cases of thoracolumbar scoliosis. Some institutions have attempted to use this test as a rapid, inexpensive screening tool for scoliosis, with sensitivity of 84% and specificity of 93% in early detection of scoliosis.⁴⁵ When forward bending consistently deviates to one side, an irritating focus in the spinal canal such as a disc herniation, a congenital anomaly, or a tumor should be suspected.

Goniometric Evaluation

Assessment of coronal plane deformity can be inferred with simple goniometric evaluation since studies of goniometric testing correlate strongly with Cobb angle measurements. Bunnell found a high correlation of 5° on scoliometer with a Cobb angle of 20°.⁴⁶ Recent studies have validated the use of goniometric evaluation of kyphosis and lordosis due to the high correlation on lateral plain films of the spine.⁴⁷

Abdominal Reflexes

Abdominal reflexes should be tested whenever there is concern for thoracic spine pathology. The patient is placed supine with their arms relaxed along the side of the body. The abdomen is stroked with a blunt instrument in each of the four quadrants around the umbilicus, starting laterally and moving diagonally toward the umbilicus. Normally, the abdominal musculature in the quadrant should contract, causing the umbilicus to deviate toward the region. Asymmetric or absent reflexes may indicate underlying cord pathology such as syringomyelia that should be further evaluated with advanced imaging.⁴⁸

Beevor's sign assesses weakness of the lower abdominal musculature, and may indicate a cord lesion at the thoracic level.^{49,50} The patient is placed supine and attempts to sit up or raise the head. A positive sign consists of the umbilicus displacing proximally as the strength of the upper rectus abdominal muscles predominate. In such situations, further workup for thoracic pathology should be pursued.

LUMBAR SPINE EVALUATION

Observation

Ask the patient to stand upright in order to determine the presence of any gross deformity. Increased or decreased

lumbar lordosis should be noted. The relationship of the pelvis to the lumbar spine should be inspected to evaluate the overall pelvic tilt.

Gait

Gait abnormalities may indicate lumbar pathology.⁵¹ With disc herniation, the patient will typically have a slow and measured gait. Decreased stride length and increased time needed from heel touch to contralateral toe lift off have been found to correlate with lumbar spinal abnormalities on gait analysis.⁵² Patients who avoid sitting and prefer to stand may have disc pathology, while those who prefer to sit or lean forward while walking are more likely to have some component of spinal stenosis. A high-steppage gait is indicative of foot drop, which may be related to nerve root compression or peripheral nerve damage.

Range of Motion

To evaluate lumbar range of motion, direct the patient to perform active movements and only perform passive range of motion testing when full active motion cannot be achieved. Ideally both evaluations can be done. Resisted movements can be performed in each direction. Pay close attention to stiffness or pain, or lack of fluidity. Newer methods attempt to measure lumbar motion exclusively without including hip motion in the measurement. Other more recent devices such as inclinometers, pelvic restraint devices, and even triaxial potentiometric systems have proven to be reliable in quantifying range of motion.^{53,54}

To assess forward flexion, ask the patient to bend forward and reach with their fingers toward their toes, and then measure the distance from the floor to the tips of their fingers. Next, test lumbar extension by asking the patient to stand upright and slowly bend backward; placing your hand midline on the lower back or allowing them to hold onto a chair helps to stabilize them. Proceed to side bending. With your hand on their posterior superior iliac spine, have the patient place their arms at their sides, and then lean first to one side and then to the other. With you and the patient in the same positions, complete the set of movements by asking the patient to rotate the trunk in both directions. When doing this, make sure the chin and shoulders remain perpendicular so that the patient is exercising the lumbar and not the cervical spine. Hip range of motion, including flexion/extension, abduction/adduction, and internal/external rotation should be assessed as well, which may reveal compounding joint pathology.

Palpation

Sit behind the patient and place your fingertips on the hips while you palpate the spinous processes with your thumbs. Palpate the iliac crests, the superior margins of which will be at the L4–L5 interspace. Also palpate the sacroiliac (SI) joint and the posterior superior iliac spine that is typically close to the S2 level. Note any tenderness, step-off, or gibbus that could suggest spondylolisthesis. In very thin patients it may be possible to palpate any lack of spinous processes, especially in the vicinity of hairy patches or areas of abnormal pigmentation, which could be suggestive of congenital anomaly. Palpate along the lateral borders of the spine to evaluate for pain emanating from the transverse processes.

Localized tenderness over the sciatic notch suggests sciatic nerve irritation, in contrast to tenderness over the axial spine or the SI joint. Tenderness over the greater trochanters is consistent with trochanteric bursitis that may mimic radicular pain. In order to rule out muscular etiologies, ask the patient to extend the neck and palpate down the paraspinal muscles adjacent to the spine. Finally, assess for pelvic obliquity and possible leg length discrepancies.

Sensation

The L1 dermatome includes the medial thigh toward the groin, the L2 dermatome is slightly more anterior and inferior, and the L3 dermatome runs medial to the patella and inferior toward the medial leg. The L4 dermatome runs down the medial leg to the medial aspect of the great toe, while the L5 dermatome includes the more lateral leg, the first dorsal webspace, and the dorsal aspect of the middle toe. The S1 dermatome most commonly includes the lateral aspect of the foot and the fifth toe. One study showed 20% sensitivity and 93% specificity of the pinprick examination for diagnosis of lumbar radiculopathy; however, these numbers increased to 36 and 92%, respectively, when the physician was made aware of the patients' MRIs prior to performing the physical examination, indicating a significant bias in diagnosis after reviewing imaging.⁵⁵

Motor

L1–L3

The L1–L3 myotomes are examined together due to their collective innervation of the iliopsoas, the primary hip

flexor. Ask the patient seated with their buttocks at the edge of their chair or examination table to lift their flexed knee upward while you resist with your hand just proximal to the knee. Compare the strength across both legs. Such lumbar spine motor examination was found to have a sensitivity between 39% and 48% and a specificity of 86% and 89%.⁵⁵

L2–L4

The quadriceps and hip adductors receive their innervations from the L2–L4 nerve roots. Evaluate quadriceps strength through knee extension while the patient remains seated. Allow the patient to sit comfortably with their knees bent while their feet are relaxed and dangling. Place one hand on the thigh and one on the anterior surface of the tibia and ask the patient to extend their leg against your resistance. Another option is to evaluate the standing patient as they rise from a *Squat*.

Hip adductors can be tested in the supine patient starting with the patient's knees extended and hips abducted so that the feet are just beyond shoulder width. Place your hands on the medial aspects of the knees and ask the patient to bring both legs together while leaving their heels on the examination table.

L4–L5

While the patient remains supine on the examination table, test hip abduction through gluteus medius strength that is controlled by the superior gluteal nerve (L5). Have the patient keep their knees extended and legs together and then have them bring their legs apart while leaving their heels on the table.

Next, ask the patient to sit for L4 and L5 testing of the tibialis anterior (TA) and the extensor hallucis longus (EHL), respectively. To test TA function, have the patient maintain their foot in dorsiflexion and inversion as you try to push their foot into plantarflexion and eversion against their resistance. After having held their foot and ankle to test the TA, move your stabilizing hand to grasp their calcaneus to test the EHL. Gently place downward pressure on the interphalangeal joint of the great toe and evaluate whether or not the patient can extend their EHL against this resistance. Another option in the ambulatory patient is to have them walk on their heels to demonstrate TA as well as EHL integrity. In some patients, weakness of the TA or EHL is only demonstrated once the muscles fatigue.

Table 5.4: A summary of lumbar neurology.

<i>Disc</i>	<i>Root</i>	<i>Sensation</i>	<i>Muscle</i>	<i>Reflex</i>
L1-2	L1	Anterior groin	Iliopsoas	
L2-3	L2	Proximal thigh	Iliopsoas, quadriceps, hip adductors,	
L3-4	L3	Distal thigh, anterior/medial knee	Iliopsoas, quadriceps, hip adductors	
L4-5	L4	Medial calf and foot	Gluteus medius, tibialis anterior	Patellar
L5-S1	L5	Lateral calf and dorsum of foot	Extensor hallucis longus, hamstrings	
S1-S2	S1	Posterior calf and lateral foot	Gastrocnemius–soleus, hamstrings	Achilles

S1

Evaluation of S1 nerve root motor function is elicited through plantarflexion or contraction of the gastrocnemius–soleus complex. With the patient seated and with their legs over the side of the examination table, ask them to plantarflex against resistance placed on the sole of the foot. Alternatively, ask the patient to walk on their toes. As noted for TA and EHL testing, in some patients, weakness of the gastrocnemius–soleus complex is only demonstrated once the muscles fatigue with repetitive muscle testing, as done through the single limb heel rise. Ask the patient to first balance themselves by holding onto a chair. Then ask them to stand on one leg and to then repeatedly rise up and down on their toes of that leg. Then repeat this on the other leg.

Reflexes

Testing for the Babinski reflex and for clonus is a standard part of the physical examination of most spine patients. In addition, reflex testing of the lower extremities should include the patellar and Achilles reflexes.

The patellar tendon reflex is indicative of L4 function. Have the patient sit beyond the edge of their examination table or chair with their legs relaxed and their knees bent, making sure that their feet hanging down but not touching the ground. Identify the superficial aspect of the infrapatellar tendon and strike it the reflex hammer.

To test the Achilles reflex (S1 function) keep the patient in the seated position and hold the foot in dorsiflexion. Palpate the Achilles tendon and strike it to elicit either a plantarflexion response or a palpable tendon contraction.

Patellar and Achilles hyperreflexia are specific for detecting myelopathy (76% and 81%, respectively), but have low sensitivities (33% and 26%, respectively).¹⁴ Table 5.4 summarizes the dermatomes, muscle groups, and reflexes for each lumbar and sacral nerve root.

Dural Tension Signs

Evaluation of lumbar spinal pathology should include provocative maneuvers. Under normal circumstances, the lumbosacral nerve roots are mobile within their foraminae and exhibit progressively increasing excursion distally.⁵⁶ However, pathologic conditions such as stenosis or intervertebral disc herniation impair this mobility and cause pain. Several useful “dural tension” signs, as described below, place tension on the nerve roots to elicit symptoms.

Straight Leg Raise

The straight leg raise (SLR) is performed by placing the patient supine on the examination table, and then raising the leg with the knee fully extended to reproduce radicular symptoms between 30° and 70° of elevation (Fig. 5.8).²¹ The sensitivities and specificities of this maneuver for lumbar disc herniation are 36–97% and 11–84%, respectively.^{57–63} Part of the inconsistency with the examination relates

Fig. 5.8: Straight leg raise—a patient with a L4-5 or L5-S1 disc herniation will feel increased tension on the affected nerve root when the leg is elevated between 30° and 70°.

to the variability in defining a positive result, such as the degree of elevation at which symptoms occur or the type of symptom produced. When comparing mid-lumbar (L2–L4) to low lumbar (L5–S1) regions, the SLR test is much more sensitive and specific for low lumbar root impingement.⁶²

Cecin's sign is a variation of this tension examination in which a Valsalva maneuver is incorporated as well. The standing patient is asked to flex the lumbar spine forward to the point where pain is experienced, and then asked to cough to simulate the Valsalva maneuver. Worsening radicular pain is considered a positive Cecin's sign, which has a sensitivity of 73% and a specificity of 95% in patients with lumbar disc herniation proven on MRI.²⁴

Lasègue's Sign, Bowstring Sign

Several other variations on the SLR test exist including the Lasègue's sign and the Bowstring sign.

Since a specific maneuver was never described by Lasègue himself,⁶⁴ the sign attributed to him has variable descriptions in the literature. One version of the positive Lasègue's sign refers to radicular pain elicited when the foot is dorsiflexed after the leg had been raised to the point of symptom reproduction and then slightly lowered. Foot dorsiflexion adds further tension to the irritated lumbosacral nerve root such that the leg symptoms are reproduced (Fig. 5.9).^{61,65} A second description involves raising the leg with knee semi-flexed and then extending the knee until symptoms are reproduced.

The Bowstring sign elicits pain during a leg raise with a semi-flexed knee followed by application of manual pressure within the popliteal fossa to tension the tibial nerve.⁶⁶ In contrast, placing tension on the medial and lateral hamstring tendons instead should not recreate pain in a patient with organic spinal pathology.⁶⁷

When correlated with intraoperative pathologic findings, the Lasègue's sign and Bowstring sign had 71% and 69% specificity for lumbar disc herniation, but did not assist with preoperatively identifying the location of the disc herniation relative to the nerve root (central, axillary, foraminal, etc.).⁶¹

Crossed Straight Leg Raise Sign, Crossed Lasègue's Sign

The crossed SLR sign, or well-leg raise sign, utilizes the fact that the SLR not only stretches the ipsilateral nerve root,

Fig. 5.9: Lasègue's sign—a patient with L4–5 or L5–S1 disc herniation will feel additional increased tension on the affected nerve root during a straight leg raise when the foot is dorsiflexed.

but also causes lateral pull on the dural sac that subsequently causes contralateral nerve root stretch.^{68,69} With this examination, an SLR is performed on the contralateral side, but symptoms are produced in the symptomatic leg. Sensitivity has been shown to be low, ranging from 4% to 42%, but with specificity higher at 85–100%.^{58–62,68,69} The crossed Lasègue's sign has been associated with accurate preoperative classification of contained versus uncontained disc herniation.⁷⁰

Femoral Nerve Stretch Test

The reverse SLR, or femoral nerve stretch test, can be used to evaluate lesions involving the more proximal L2–L4 nerve roots that innervate the femoral nerve.⁷¹ Since the more proximal nerve roots have less gliding excursion, the supine SLR is not effective in localizing them. However, the femoral nerve can be more specifically tested by placing the patient prone, passively flexing the knee, and then extending the hip. This maneuver places tension on the femoral nerve and should recreate anterior thigh pain coming from L2 to L4 nerve root irritation (Fig. 5.10). Sensitivity for detecting proximal lumbar nerve root compression is 50%, but with 100% specificity.⁶² Since this maneuver reduces tension on the sciatic nerve, pain radiating down the leg should be reduced. Hence, complaints of exacerbation of distal pain with this test may indicate a nonorganic etiology of pain.⁶⁷ Similar to the crossed SLR sign, a crossed femoral nerve stretch test may aid in the diagnosis of proximal lumbar disc herniation.⁷²

Fig. 5.10: Femoral nerve stretch test—a patient with a lumbar disc herniation at L1–L3 will feel increased tension on the affected nerve root when the hip is extended due to the increased stretch on the femoral nerve.

Sacral/Anal Evaluation

In patients with suspected spinal cord trauma, it is imperative to evaluate anal tone, saddle sensation, and sacral reflexes including the bulbocavernosus reflex and anal wink. The perianal region is innervated in a concentric circular distribution via the S3–S5 nerve roots (*see* Fig. 5.1). In the post-traumatic patient, resolution of spinal shock may be evaluated through the return of the bulbocavernosus reflex, in which reflex anal contraction is elicited with bladder trigone stimulation. This may be accomplished by squeezing the glans penis, tugging on a bladder catheter, or tapping the mons pubis. The anal wink reflex is mediated via the S2–S4 nerve roots, and causes anal contraction in response to perianal skin light touch. Patients with sacral sparing following trauma, or preservation of sacral motor or sensory function, are considered to have an incomplete spinal cord injury, which has significant prognostic value.⁷³

Sacroiliac Joint Assessments

The SI joint is a potential source of pain since it anchors the sacrum to the ilium. Since the joint itself is innervated with nociceptors from the lumbosacral nerve roots,⁷⁴ pain may also be referred to the SI from the spine. Sacroiliac pain is common, particularly after twisting or repetitive forward leaning with lifting, and must be accurately recognized. Tenderness to palpation directly over the SI must be

Fig. 5.11: Gillet test—in a patient with sacroiliac dysfunction, with hip flexion the posterior superior iliac spine does not rotate posteroinferiorly with respect to the sacrum, and the physician's thumb on the patient's posterior superior iliac spine does not rotate inferiorly.

distinguished from tenderness of the axial spine, the sciatic notch, the iliac crest, or the greater trochanter. Sacroiliitis may also be an early diagnostic feature of ankylosing spondylitis or other spondyloarthropathies.

Gillet Test

The Gillet test is used to assess the range of motion and movement of the SI joint, and it has over 85% intra- and interexaminer reliability.^{75–77} The patient stands upright with feet apart. The examiner sits behind the patient, places one thumb over the second sacral spinous process, and one thumb under the ipsilateral posterior superior iliac spine. The patient then flexes the ipsilateral knee and hip, bringing the thigh toward the abdomen (Fig. 5.11). Normally, with hip flexion the posterior superior iliac spine will rotate posteroinferiorly with respect to the sacrum, bringing the physician's posterior superior iliac spine thumb inferiorly. The absence of this movement is considered a positive test and is a sign of decreased or absent SI joint mobility.^{78,79} In asymptomatic individuals, the Gillet test was found to have a false-positive rate of 16%, with significantly higher false-positives in women (26%) compared to men (4%).⁷⁸ Sensitivity was found to be 8%, with specificity of 93% for detecting innominate torsion, but did not address assessment of SI joint hypomobility.⁸⁰ A study comparing the test to anesthetic blocks found sensitivity for detecting mobility of the SI joint to be 43%, with 68% specificity.⁸¹

Fig. 5.12: Patrick test—in a patient with sacroiliac pain, the position of flexion, abduction, and external rotation will recreate their symptoms.

Patrick Test (FABER)

The Patrick test assesses SI joint pathology. The patient is placed supine and the hip is flexed, abducted, and externally rotated (FABER) until the lateral malleolus is placed on the contralateral knee, and light pressure is placed on the ipsilateral knee to assume a more externally rotated position (Fig. 5.12). A positive result is one that reproduces SI joint pain. This test has been found to have a sensitivity of 54–77% and a specificity of 16–100% for detecting sacroiliitis.^{81–84}

Gaenslen's Test

The pelvic torsion test, or Gaenslen's test, is performed with the patient supine and the affected side of the pelvis partially off of the examination table. The contralateral hip and knee is flexed to the chest to stabilize the lumbar spine, and the examiner applies pressure to the ipsilateral hyperextended thigh (Fig. 5.13). This test is considered positive if it reproduces pain in the SI joint.⁸⁵ Sensitivity for detection of sacroiliitis in MRI-evaluated patients is low at 36–44%, but since specificity is 75–80%,⁸² the test has been shown to be reliable.⁷⁷

Yeoman's Test

The patient is placed prone, and the ipsilateral posterior superior iliac spine is stabilized while the hip is hyperextended with the knee joint flexed. This maneuver that

Fig. 5.13: Gaenslen's test—in a supine patient, the contralateral hip and knee is flexed to the chest, and the examiner applies pressure to the ipsilateral hyperextended thigh. This causes pain in a patient with sacroiliac pain.

distracts the pelvic wing and thereby placing stress within the SI joint is considered positive if SI pain is reproduced.⁸⁵ There have been no studies in the literature that assess the sensitivity or specificity of Yeoman's test.

Schober's Test

The Schober's test, or skin distraction test, is an examination of lumbar spinal mobility. As initially described, the level of the posterior superior iliac spine is marked in the midline with the patient fully erect and a second point 10 cm above is marked as well. The patient then fully flexes, and the increased distance between the points is measured. A modified Schober's test, now almost exclusively used, adds a third mark 5 cm below the posterior superior iliac spine, and measures the excursion between the superior and inferior marks.⁸⁶ In a patient with normal spinal mobility, there should be at least 5–6 cm of excursion between the points, although this has been shown to decrease with age.⁸⁷ The Schober's index has a negative correlation with the number of vertebral levels involved in ankylosing spondylitis, indicating decreased lumbar range of motion with increasing levels.⁸⁸ This test has an inter-observer reliability of 71–90%^{89,90} with high intraobserver repeatability⁹¹ and reliability of 94%.⁸⁹ It has similarly been found to be useful for differentiating axial from peripheral psoriatic arthritis with sensitivity of 51% and specificity 78%.⁹²

WADDELL'S SIGNS

The Five Signs

Successful management of the spinal disorder must address not only the organic pathoanatomy, but also the underlying nonorganic, psychosocial, and behavioral issues. Waddell developed a set of physical signs of nonorganic back pain used to further evaluate patients presenting with back pain with the goal of identifying underlying psychological and social etiologies that may compound organic pathology.⁹³ Ultimately, these signs may be used to identify patients requiring psychological evaluation rather than surgery. The five types of examination include tenderness, simulation, distraction, regional neurologic disturbance, and overreaction. A single isolated positive finding may in fact be due to an organic cause. However, when three or more of these signs are positive, a nonorganic cause of back pain is more likely.

1. Tenderness—organic causes usually relate to a skeletal structure or neuromuscular region, and typically follow a specific dermatomal distribution due to nerve root irritation. Nonorganic causes should be suspected with *superficial* tenderness, or that which exists over a *nonanatomic* region.
2. Simulation—testing that gives the appearance of a provocative maneuver but that should not actually reproduce pain from an anatomic perspective. *Axial loading* of the occiput resulting in low back pain is an example of such testing.
3. Distraction—examination while the patient is distracted can provide useful information regarding consistent or inconsistent symptoms. For example, radicular pain elicited during a supine *SLR* that disappears with a seated *SLR* may not have an anatomic basis.
4. Regional disturbances in physical findings are those that do not follow a neurologic-anatomic distribution. For example, weakness or sensory loss in a “stocking” distribution as opposed to a peripheral nerve or nerve root distribution should be evaluated for peripheral neuropathy. This can be due to a medical comorbidity (diabetic neuropathy, ischemia) or multiple nerve root involvement.
5. Overreaction to physical examination and provocative maneuvers include excessive verbalization, shaking, tremor, or facial expression.

Causes

Some studies have supported the association of Waddell's signs with underlying hypochondriasis and hysteria in men but not in women.⁹⁴ However, an evidence-based review showed that, while Waddell's signs are associated with greater pain levels, decreased functional levels, and worse outcomes for conservative and for operative treatment, they do not specifically correlate with psychological distress, secondary gain, and nonorganic pathology.⁹⁵ Care must be taken before any conclusions can be drawn when these signs are elicited, and their presence should not preclude complete examination of the patient.

KEY POINTS

- A thorough physical examination of the spine is paramount to appropriate care of the spine patient. In many cases, the diagnosis can be made before the examination is complete, but every step of the evaluation should be made to avoid missing any key areas of the patient's disease process.
- A vast amount of information can be obtained through careful observation of a patient prior to beginning the examination. Many patients are not aware that you are examining how they walk or move before or after the evaluation and this can help you understand where their pain is.
- In general, cervical or lumbar disc herniation leads to specific nerve root involvement and will likely lead to pain or paresthesias in one dermatome, with weakness in one muscle group, and one blunted reflex. In contrast, cervical or lumbar spinal stenosis will lead to paresthesias in multiple dermatomes, weakness in multiple muscle groups, multiple areas of hyperreflexia (cervical), or multiple blunted (lumbar) reflexes.
- Specific provocative tests on physical examination provide a higher sensitivity and specificity than the routine examination. Patients with positive localizing tests are more likely to have imaging indicative of spinal pathology.
- Waddell's signs for nonorganic back pain are helpful to determine if a patient's pain is unlikely to be originating from organic spinal pathology. The presence of these signs does not necessarily mean that the patient is malingering but do suggest that their pain may be due to factors unrelated to the spine.

INTRODUCTION

Electrodiagnostic examination is composed of two distinct but complementary techniques: nerve conduction studies (NCS) and needle electromyography (EMG).

During NCS, the electrical responses evoked by nerve stimulation in muscle and nerve are recorded and analyzed. Both motor and sensory NCS are performed. Whenever motor NCS are performed, recording electrodes are placed over a muscle and its tendon.

For all routine motor NCS, a small muscle of the hand or foot serves as the recorded muscle, and the nerve supplying it is stimulated at two points along its course: the elbow and wrist in the upper extremity, and the knee and ankle in the lower extremity.

Nerve conduction studies can be used to (1) diagnose diffuse polyneuropathy, (2) pinpoint a focal nerve lesion, and (3) evaluate the severity of a known nerve injury.^{1,2} Polyneuropathy is diagnosed electrophysiologically by abnormalities in multiple nerves. The pattern is usually diffuse and symmetrical. Focal lesions (entrapments) are primarily myelin abnormalities caused by ischemia, or by myelin sheath distortion or slippage. Examinations of a short segment are optimal. The distal segment may conduct normally or abnormally, depending on the severity of the lesion. Proximal nerve lesions and the brachial

plexus lesions are difficult to document using routine distal conduction examinations. H reflexes and F-waves may be helpful in these conditions (these are discussed later in the chapter).^{3,4} If a response can be evoked across the site of an injury, this rules out a complete lesion. If adequate time has elapsed for severed fibers to undergo Wallerian degeneration (3 or 4 days), an intact response distal to the injury suggests something other than a complete lesion.⁵

For sensory NCS, either a sensory nerve or a mixed nerve (motor and sensory nerve) is stimulated at one point. Sensory nerve action potentials (SNAPs) are recorded at a set distance along the nerve fibers. The cell bodies for the motor axons are situated within the anterior horns in the spinal cord. On the other hand, the cell bodies for the sensory axons are located within the dorsal root ganglion (DRG). Lesions within the spinal canal (myelopathy and radiculopathy) involve sensory fibers that are proximal to their cell bodies in the DRG, rather than distal to them. These lesions do not affect the SNAP amplitude because the injured sensory fibers degenerate centrally from the lesion site rather than peripherally, thus leaving the peripheral sensory fibers intact. By contrast, lesions involving the plexuses and peripheral nerves cause sensory fibers to degenerate distally from that point, resulting in low-amplitude SNAPs or a failure to elicit SNAPs.

FACTORS INFLUENCING ELECTRODIAGNOSTIC STUDIES

Age

Conduction velocity in newborns is approximately half of adult values; velocity increases until normal adult values are attained by 3–5 years of age. In adults, the conduction values vary slightly from decade to decade, but this is usually of little significance until over age 60 years. Older subjects usually have slower conduction and lower-amplitude responses, and this slower conduction is especially evident in sensory studies.

Temperature

Many studies have demonstrated the effect of temperature on human conduction velocity.^{6–8} Velocity is proportionally related to temperature at a rate of 0.7–2.4 m/s for each degree centigrade. This effect decreases at higher temperatures, becoming less significant above approximately 30°C skin temperature. The shape of the response is also affected. Latency, duration, and amplitude—all increase as temperature falls.⁹

Gender

The difference between male and female subjects was found to be significant in a few studies. This included sensory studies of median, ulnar, radial, sural, and superficial peroneal nerves^{10,11} and in motor studies of the ulnar nerve.¹² Generally, females are found to have higher amplitudes, but this may be due to females generally having smaller extremities resulting in female nerves being closer to the recording electrodes.

NEEDLE EMG

Unlike NCS, needle EMG only assesses the motor fibers. During needle EMG, a recording needle electrode is inserted into various muscles and the electrical activity generated within them, either spontaneous or voluntary, is evaluated visually and aurally.

The assessment of needle EMGs is divided into three phases: (1) the insertion phase, (2) the “at rest” phase, and (3) the activation phase. During the insertion phase, the electrical activity resulting from needle movement in a relaxed muscle is studied. In normal muscles, each insertion injures several individual muscle fibers, thus generating

a small burst of electrical potentials referred to as insertional activity. During the “at rest” phase, there is normally electrical silence. However, various types of spontaneous activity (fibrillation potential and positive sharp potential) occur with many disorders of the neuromuscular system. Fibrillation potentials are spontaneous and usually fire regular action potentials in individual muscle fibers. Fibrillation potentials and positive sharp potentials can be observed in both myopathic and neuropathic processes. Fasciculation potentials are spontaneous action potentials and are indicative of motor unit irritation rather than denervation. During the motor unit potential (MUP) activation phase, the muscle being assessed is contracted by the patient at the examiner’s request, thereby causing voluntary MUPs. Motor unit potentials are evaluated in terms of their firing characteristics and their configurations.

Many electromyographers are able to diagnose radiculopathy and entrapment neuropathy with needle EMG abnormalities in a myotomal distribution.¹³

Involvement of the reflex arcs, anterior horn, lateral corticospinal tracts, nerve roots, and cauda equina is often assessed by electrophysiological examination. The relevant electrodiagnostic parameters include the H reflex, F-wave, central motor conduction time (CMCT), and cauda equina conduction time (CECT). In conditions involving cervical myelopathy, it is difficult to accurately diagnose the specific level of the lesion. However, evoked spinal cord potentials using peripheral nerves, transcranial stimulation, and spinal cord stimulation have been used at an attempt to diagnose the specific level of the lesion.^{14,15}

H REFLEX

The H reflex is a monosynaptic segmental reflex named after Dr Johann Hoffmann, a German neurologist who described it in 1918.¹⁶ Although it is present in many nerves in newborns, the response disappears by adulthood. In the adult the H reflex is usually studied in the tibial nerve, although it has also been studied in the flexor carpi radialis muscles. It is analogous to the ankle tendon reflex. There is a single synapse in the spinal cord, which results in an efferent discharge of the S1 (and possibly L5) anterior horn cells, whose fibers travel through the sciatic nerve to the gastrocnemius, soleus, and other tibial nerve-innervated muscles. The H reflex can only be obtained consistently in adults by stimulating the tibial nerve in the popliteal fossa. It is evoked at low stimulus intensity and its maximal amplitude exceeds that of the direct muscular response compound muscle action potentials (CMAPs). At higher

Fig. 6.1: H reflex. Demonstration of increasing stimulus strength during progression from the lowest to highest sweep. Note the appearance of the H reflex at low-stimulus intensity and its subsequent inverse relationship with compound muscle action potentials with increasing stimulus intensity.

stimulus intensities, the amplitude decreases and varies inversely with the CMAP amplitude. The H reflex should be absent at supramaximal stimulation. When elicited, the response remains constant if the stimulus is maintained constant (Fig. 6.1).

By contrast, the F-wave is best evoked with supramaximal stimulation and its amplitude is only a fraction of the CMAPs. Moreover, it is not constant and varies in amplitude and latency, even with constant stimulus.

Typically, the sacral plexus, sciatic nerve, and tibial nerve are all evaluated by the H reflex.

F-WAVE

The F-wave was first described by Magladery and McDougall in 1950¹⁷ and represents long-latency responses present in many nerves in the adult. Unlike the H reflex, F-waves have no sensory component and are not the result of a reflex arc. Instead, they are thought to represent anterior horn cell depolarization caused by antidromic stimulation of motor fibers. F-waves must be distinguished from H reflexes. F-waves are best evoked by supramaximal stimulation, and the responses are small compared with the direct muscular response (CMAPs). F-waves are not constant, they vary in latency and amplitude, and they are not always present with each stimulus (Figs. 6.2A and B). F-waves provide an opportunity to measure conduction along the most proximal segment of a nerve, including the root.

This makes it useful for pathology involving the nerve root or proximal nerve pathology.

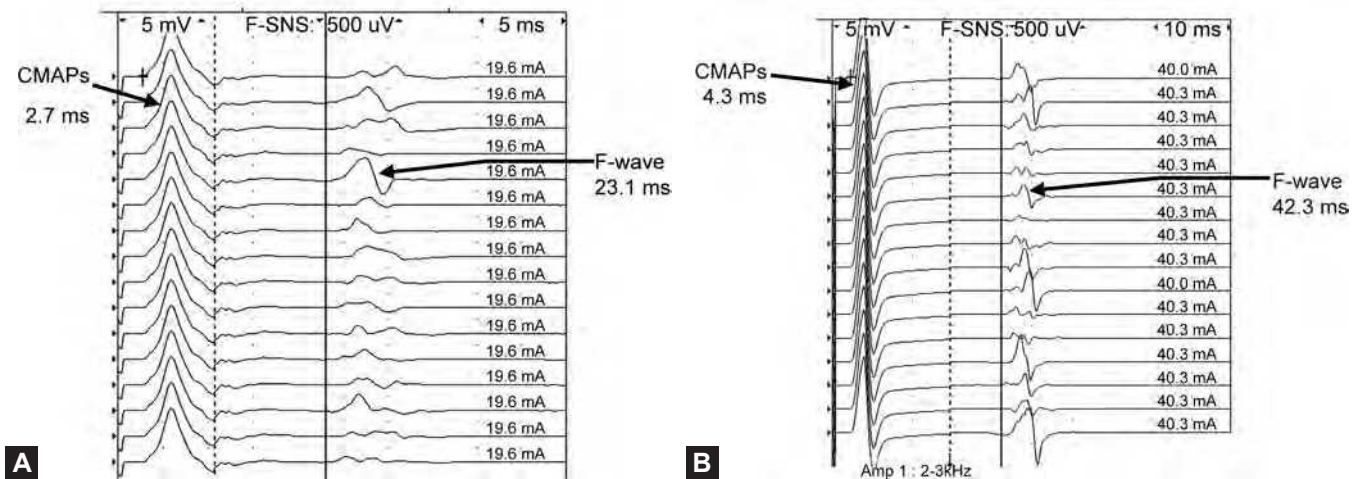

MOTOR-EVOKED POTENTIALS

Beginning in 1980, techniques were developed to stimulate the motor cortex using surface stimulation. Merton and Morton utilized brief, high-voltage stimuli.¹⁸ Subsequently, Barker et al. developed magnetic stimulation.^{19,20} These methods have been used to stimulate cortical structures as well as the spinal cord and root regions. The safety, side effects, reliability, and clinical utility of these procedures are still being evaluated. They provide an assessment of descending motor pathways from the cortex, through the spinal cord and to the periphery. High-voltage methodology requires an output of 750 V and low-output impedance. Magnetic stimulation is via a flat helical coil. The high-voltage technique provides optimal stimulus localization. However, it is difficult to precisely localize the point of stimulation with the magnetic stimulation procedure. The advantages of the magnetic stimulation procedure are that it is painless and can be delivered without skin contact.

CENTRAL MOTOR CONDUCTION TIME

Transcranial magnetic stimulation allows noninvasive investigation and objective assessment of the efferent nerve functions through the corticospinal tract.²¹ Abnormal CMCT after magnetic stimulation was reported in up to 84% of patients with cervical myelopathy.²²⁻²⁴ It is common practice to calculate the CMCT of the proximal limb muscle by subtracting the motor-evoked potential (MEP) latency of the magnetic neck stimulation from the magnetic cortical stimulation.²⁵

Cervical root impulses in the foraminal region have been elicited by magnetic neck stimulation.²⁶ When this method of investigation is used in the CMCT, false-positive results can occur in patients with concomitant intraforaminal cervical root lesions. Thus, Ofuji et al. reported an alternative technique to calculate the CMCT using tendon reflex latency (T-response).²⁷ Central motor conduction time is measured by subtracting the peripheral conduction time, which is calculated using the T-response for the biceps brachii muscle. For the distal limb muscles, the CMCT is calculated by the F-wave (Figs. 6.3A and B). However, recording the F-wave from the proximal upper limb muscles is technically demanding.

Figs. 6.2A and B: F-wave. (A) Ulnar nerve stimulation at the wrist with surface recording from the abductor digiti minimi (ADM). Compound muscle action potentials (CMAPs): direct response, the F-wave is variable, changing from response to response. CMAP latency is 2.7 ms. The shortest F-wave latency is 23.1 ms. Peripheral conduction time (PCT) is calculated from the CMAPs and F-wave after supramaximal electrical stimulation of the ulnar nerve at the wrist for ADM. The PCT is 12.4 ms, calculated as $(2.7 + 23.1 - 1)/2$. (B) Tibial nerve stimulation at the ankle with surface recording from the abductor hallucis (AH). Compound muscle action potentials: direct response, the F-wave is variable, changing from response to response. CMAP latency is 4.3 ms. The shortest F-wave latency is 42.3 ms. PCT is calculated from the CMAPs and F-wave after supramaximal electrical stimulation of the tibial nerve at the ankle for AH. PCT is 22.8 ms, calculated as $(4.3 + 42.3 - 1)/2$.

Figs. 6.3A and B: (A) MEPs elicited in the ADM of a normal volunteer by magnetic stimulation of motor cortex CMCT in the upper extremities (ADM) is 5.5 ms: 17.9-12.4 (B) MEPs elicited in the AH of a normal volunteer by magnetic stimulation of motor cortex CMCT in the lower extremities (AH) is 12.5 ms: 35.3-22.8.

CLINICAL APPLICATION OF CMCT

Central motor conduction time can be used to electrophysiologically evaluate the corticospinal tract. Abductor digiti minimi (ADM) muscles are mainly innervated from C8 and T1 segments, whereas abductor hallucis (AH) muscles are mainly innervated from S2 and S3 segments.

Therefore, corticospinal tract conduction block at the level of or rostral to the C7 segment results in the prolongation of CMCT in upper extremities (ADM). Corticospinal tract conduction block at the level of or caudal to the T2 segment results in the prolongation of CMCT in lower extremities (AH) and a normal CMCT in upper extremities (ADM). Kaneko et al.²⁸ proposed a mechanism for prolonged

Table 6.1: Normal value of CMCT.

CMCT (ms)	Kaneko et al.	Nakanishi et al.
ADM	4.2±1.1	7.2±1.4
AH	11.1±1.5	14.2±2.0

(ADM: Abductor digiti minimi; AH: Abductor hallucis).

CMCT in compressive cervical myelopathy that involves a minor slowing of conduction in the corticospinal tract after transcranial electric stimulation. The slowing of spinal motor neuron firing of multiple corticospinal descending volleys could explain the prolonged CMCT without pronounced slowing of corticospinal conduction in compressive cervical myelopathy. Table 6.1 shows normal values for CMCT in the upper and lower extremities.^{28,29}

Nakanishi et al.²⁹ measured CMCT in the upper extremities (ADM) and CMCT in lower extremities (AH) in 20 patients with compressive thoracic myelopathy (CTM), 92 patients with compressive cervical myelopathy (CCM), and 18 control subjects. Central motor conduction time in the lower extremities (AH) of patients with CTM were significantly longer than in control subjects, although no significant differences were observed for upper extremities (ADM). Both the CMCT in upper (ADM) and lower extremities (AH) of patients with CCM were significantly longer than those of controls. The ratio of CMCT in upper extremities (ADM)/CMCT in lower extremities (AH) in the CTM group was significantly lower than in the other groups.

In contrast to the above study, Taniguchi et al. evaluated patients with CTM by recording MEPs from the erector spinae muscles at 12 serial vertebral levels and compared the results with data from normal subjects.^{30,31} The examiners were able to identify all cases of CTM at lesions rostral to the T10–11 level, and were not able to identify lesions at or caudal to T10–11.

CAUDA EQUINA CONDUCTION TIME

Lumbar spinal stenosis (LSS) is a degenerative disease of the spine, and magnetic resonance imaging (MRI) is the method of choice for evaluating this condition. However, asymptomatic LSS is not an uncommon finding in the healthy population.³² In addition, the severity of MRI findings does not always correlate with symptoms associated with LSS.³³ Electrodagnosis is an important testing modality in the investigation of LSS, and numerous studies have suggested that a slowing or blocking of root nerve conduction is associated with neurogenic claudication^{34–42} (Fig. 6.4).⁴³

Fig. 6.4: Cauda equina conduction time using F-waves was calculated by subtracting the peripheral conduction time (PCT) from the onset latency of the motor-evoked potentials (MEPs) after the first sacral magnetic stimulation. The onset latency of MEPs after the first sacral magnetic stimulation is 20.0 ms. Cauda equina conduction time is 2.8 ms: 22.8–20.0.

SPINAL CORD-EVOKED POTENTIALS
PN-SCEPs: Peripheral Nerve Stimulation

Gasser and Graham recorded potentials from the dorsum of the spinal cord of cats evoked by stimulation of a dorsal root.⁴⁴ Subsequently, many investigators have analyzed spinal potentials evoked by stimulation of both the dorsal root and peripheral nerves.^{45,46} Shimoji et al. reported a safe and simple method of recording spinal cord-evoked potentials (SCEPs), both for the clinical use in the diagnosis of spinal diseases and for basic research on the origin of SCEPs.⁴⁷ However, the action potentials that result from peripheral nerve stimulation are usually too small to allow extradural observation. Thus, attempts have been made to record spinal-evoked potentials of high amplitude. High-amplitude SCEPs are most accurately and safely recorded when the stimulating electrode is inserted into the epidural space.

MN-SCEPs: Spinal Cord-Evoked Potentials after Median Nerve Stimulation

MN-SCEPs are recorded intraoperatively, with the median nerves being stimulated at the wrist (Fig. 6.5). The stimulus intensity is set at 1.5 times that required to produce a thumb twitch in an awake patient.

Fig. 6.5: MN-SCEPs. Normal MN-SCEPs consist of the spike (P1N1) and subsequent slow negative deflection (N2) in the posterior recording.

Fig. 6.6: SC-SCEPs. Normal SC-SCEPs consist of two negative deflections (N1, N2) in the posterior recording.

Fig. 6.7: TES-SCEPs. Normal TES-SCEPs consist of one negative deflection in the posterior recording.

SC-SCEPs: Spinal Cord Stimulation

Since the time Bremer reported the first spinal electrogram, the importance of its origin in various animals has been debated.⁴⁸ Brust-Carmona et al. examined in detail the origin of each component of spontaneous spinal electrograms in cats.⁴⁹ The recording of spinal electrograms with surface leads from the skin is not possible in humans because of the small amplitude of the spinal electrogram and interference from other sources.

Magladery et al. obtained action potentials from the dorsum of the spinal cord with electrodes introduced intrathecally into the subarachnoid space of human

volunteers.⁵⁰ However, this method involves many risks and is not amenable to routine clinical utilization.⁵⁰ Shtark recorded spontaneous spinal electrograms in humans using electrodes introduced into the epidural space; however, details of the electrode placement were not described in this report.⁵¹

SC-SCEPs represent an aggregate of conducted potentials that originate in both sensory and motor fibers of the white matter of the spinal cord (Fig. 6.6). Consequently, the amplitude and conduction velocity of the conducted SCEPs is likely to decrease in proportion to the number of injured nerve fibers.⁴⁹

TES-SCEPs: Transcranial Electric Stimulation

Levy recorded SCEPs from the human spinal cord evoked by transcranial stimulation or direct stimulation of the cortex (Fig. 6.7).⁵² These stimulation methods primarily activate the pyramidal system in the anterior spinal artery territory of the spinal cord.^{53,54} A common use for this technique is intraoperative monitoring of the spinal cord during procedures that may result in spinal cord injury. For procedures such as these, PN-SCEPs and SC-SCEPs have been shown to be incomplete indicators.

CASE

A 62-year-old man with a 24-month history of progressive numbness and clumsiness of both hands and with a gait disturbance was evaluated in our hospital. He had no

Fig. 6.8: Sagittal T2-weighted MRI showing spinal cord compression at the C4-5 intervertebral level and a high-intensity signal change.

history of trauma. On admission, neurologic examination revealed hypesthesia and hypalgesia below the forearms in the C6 dermatomes and bilateral biceps weakness. Biceps tendon reflexes were normal, triceps tendon reflexes were hyper-reflexive, and Hoffmann's reflex was present bilaterally. Sagittal T2-weighted MRI showed spinal cord compression at C4–C5 and C5–C6 from ligamentum flavum hypertrophy (Fig. 6.8). An area of high-signal intensity was observed in the spinal cord at the C4–5 level. The patient underwent a C3–C7 laminoplasty. MN-SCEPs, TES-SCEPs, and SC-SCEPs were recorded intraoperatively. Abnormalities were observed in all SCEPs at the C4–5 intervertebral level (Fig. 6.9).

KEY POINTS

- Postganglionic axon lesions (the plexuses and more peripheral nerves) cause sensory fibers to degenerate distally from that point, resulting in low-amplitude SNAPs or a failure to elicit SNAPs.
- Many electromyographers are able to diagnose radiculopathy and entrapment neuropathy with needle EMG abnormalities in a myotomal distribution.

■ KEY REFERENCES

Shinomiya K, Furuya K, Sato R, et al. Electrophysiologic diagnosis of cervical OPLL myelopathy using evoked spinal cord potentials. *Spine.* 1988;13:1225-33.

A five-pole recording electrode was placed in the cervical epidural space. The stimulation sites were the thoracic epidural space for conductive SCEPs, the median nerve at the elbow for segmental SCEPs. New findings, which could not be observed by roentgenograms, myelography, and CT scan, were detectable using this technique.

Satomi K, Okuma T, Kenmotsu K, et al. Level diagnosis of cervical myelopathy using evoked spinal cord potentials. *Spine.* 1988;13:1217-24.

The SCEPs resulting from both median nerve and spinal cord stimulation were recorded from the interlaminar yellow ligaments posteriorly or intervertebral discs anteriorly on patients with cervical myelopathy in order to determine the most significant lesion in the spinal cord electrophysiologically. The normal MN-SCEPs consisted of P1N1 and N2(P2) deflections, while normal SC-SCEPs consisted of N1 and N2 deflections. With these techniques, the level diagnostic rates of primary lesions were 94.7% in posterior recordings.

Interventional Spinal Diagnostics and Therapeutics

INTRODUCTION

Low back pain affects 70–85% of adults at least once in their lifetime.^{1,2} Neck pain is also common in the adult general population, with typical 12-month prevalence estimates from 30% to 50%.^{3,4} Both low back pain and neck pain comprise axial pain, which is rampant in present society due to increasing life expectancy and sedentary lifestyle. Men and women are equally afflicted by axial pain.⁵

Axial pain may be associated with radicular pain in some common conditions that include disc herniation, degenerative disc disease, facet disease, instability, spondylolisthesis, and other miscellaneous conditions. Acute spinal pain of a nontraumatic origin has a good prognosis for spontaneous recovery when it is not associated with significant neurologic deficits. One-third of the patients typically recover within 1 week, whereas two-thirds recover within 2 months. With respect to those with disc herniations and spinal pain, only 10% experience pain beyond 6 weeks.⁶ Majority of the patients can be treated successfully with nonoperative measures including rest and physical modalities of treatment and rehabilitation. However, a small proportion of patients with neck and back pain will not respond to these conservative measures and will continue to experience discomfort beyond 3 months and about 1.2% remain disabled by the end of a year.⁷

These selected groups of patients with disabling axial and/or radicular pain would require diagnostic evaluation. The diagnostic ladder for evaluation of such patients has been elucidated by Carragee and Cohen.⁸ The “primary diagnostic evaluation” usually involves screening for “red flags” by history and clinical examination. If this evaluation is negative, patients are put on nonoperative treatment as mentioned above. Patients who do not recover good function in due course undergo “secondary diagnostic evaluation.” This evaluation identifies serious psychological barriers to recovery and definitely rules out conditions that may result in neurologic injury or structural failure using appropriate imaging modalities. If primary and secondary evaluations fail to reveal a serious structural problem then a “tertiary diagnostic evaluation” is undertaken.⁸

In the absence of definitive diagnosis despite a thorough clinical examination, preliminary investigations, and magnetic resonance imaging (MRI), “special diagnostic tests” can be helpful in arriving at a conclusion. Isolating the source of pain can be a diagnostic challenge even with the available advanced imaging modalities. Interventional spinal procedures may constitute a major part of diagnostic armamentarium in the form of “special diagnostic tests” for locating the pain generator. In contrast to the mixed picture provided by history, physical examination,

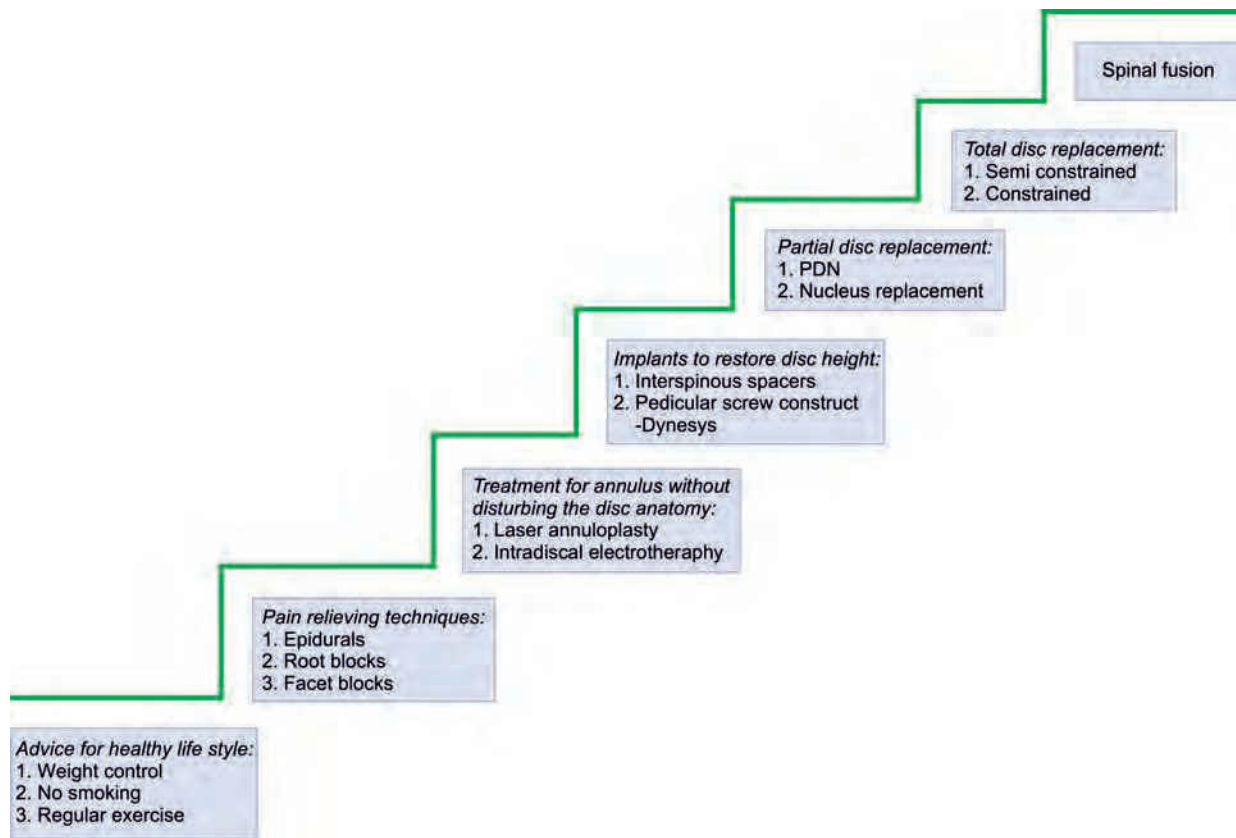

Fig. 7.1: Stepladder treatment plan for pain management for degenerative disc disease.

imaging, and nerve conduction studies in nonradicular pain, controlled diagnostic blocks have been shown to determine the cause of pain in as many as 85% of the patients while the other 15% were investigated with other available imaging modalities.⁴ Interventional therapeutics in the management of spinal disorders comes halfway between nonoperative modalities of treatment and definitive operative procedures. This is clearly highlighted by the therapeutic stepladder for the management of degenerative disc disease (Fig. 7.1).

In this chapter, we discuss the rationale and method of diagnostic procedures used to identify the source of axial pain syndromes in patients without serious underlying spinal pathologies such as infection and tumors. We also delve into therapeutic procedures to treat the same.

RELEVANT ANATOMY

Pain Generator Concept

The identification of the precise “pain generator” is a concept that is central to diagnostic evaluation and may influence

the choice of treatment. It is, however, controversial as some authors believe that the “pain generator” cannot be the sole factor in determining the seriousness and the disability associated with axial pain. The other determinants could be psychological or other neurophysiologic contributors. Despite thorough clinical examinations and advances in diagnostic technology, these “pain generators” may be difficult to identify.

Kuslich and colleagues⁹ studied 193 patients using local anesthetic (LA) to define and identify the pain source in these patients. They identified intervertebral discs, facet joints, ligaments, fascia, muscles, and nerve root dura as tissues capable of generating and transmitting pain in the low back region.⁹ The intervertebral disc, zygapophyseal joint, and sacroiliac joint are believed to be common pain generators in axial low back pain, with a reported prevalence of 5–39%,¹⁰ 15–40%,¹¹ and 6–13%,¹² respectively. Similarly, axial neck pain could have the pain source in the cervical disc, uncovertebral, facet joint, ligaments, fascia, and the muscles.^{13,14} We would like to highlight some major anatomical structures that can be classed as a primary pain source.

Fig. 7.2: Axial section at the level of intervertebral disc showing possible “pain generators.”

Intervertebral Disc

Intervertebral disc is richly innervated and hence could be the potential source of pain.¹⁵⁻¹⁷ The sinuvertebral nerves innervate the posterior aspects of the disc and the posterior longitudinal ligament. These nerves originate from one or two rami communicantes close to connection with the spinal nerves just distal and ventral to the dorsal root ganglion (DRG). The posterolateral aspects of the discs receive branches from adjacent ventral primary rami and from the grey rami communicantes near their junction with the ventral primary rami.¹⁵ The lateral aspects of the discs receive other branches from the rami communicantes. Some rami communicantes cross intervertebral discs and are embedded in the connective tissue of the disc deep to the origin of psoas. Such paradiscal rami are likely to be another source of innervation to the discs. The anterior longitudinal ligament is innervated by recurrent branches of rami communicantes¹⁵ (Fig. 7.2).

Dorsal Root Ganglion

Dorsal root ganglion is a unique component of the spinal nerve, containing the cell bodies of sensory neurons. The DRG is particularly sensitive to mechanical irritation and is suspected to be a key player in radicular pain syndromes. Because the DRG typically is located within the neural foramen, foraminal disc pathology or stenosis might be more likely to result in a burning or dysesthetic type of pain involving the affected limb¹⁶ (Fig. 7.2).

Fig. 7.3: Innervation of zygapophyseal joint.

Zygapophyseal Joint

Zygapophyseal joint is a synovial joint consisting of hyaline cartilage, synovial membrane, and a joint capsule. Capsule fibers blend posteriorly with the multifidus muscle and anteriorly with the ligamentum flavum. Two medial branches from consecutive vertebral levels innervate the cervical and lumbar zygapophyseal joints. Each medial branch courses over the respective transverse process one level above its origin.¹⁷⁻¹⁹ Dorsal root ganglion and the paravertebral sympathetic ganglion are extra innervation sources of the facet joint¹⁸ (Fig. 7.3).

Sacroiliac Joint

The innervation of the sacroiliac joint is under debate. Electrical and mechanical stimulation studies suggest that the innervation arises predominantly via the L4 to S1 nerve roots, with secondary contribution from the superior gluteal nerve.^{5,19}

MEDICATION

Steroids and local anesthetics are the cornerstone for diagnostic and therapeutic spinal injections, respectively. We hereby highlight some key features of these drugs, which would help our readers in choosing the medication.

Table 7.1: Corticosteroid preparations for spinal injections.

<i>Corticosteroid</i>	<i>Half-life (h)</i>	<i>Brand name</i>	<i>Description</i>	<i>Common dose (mg)</i>
Methylprednisolone acetate	12–36	Depo-Medrol	Particles densely packed; smaller than red blood cells; not prone to aggregation; contain benzyl alcohol (potentially neurotoxic); may not completely dissolve	20–80
Triamcinolone diacetate	12–36	Aristocort	Particles vary greatly in size; form aggregations	40–120
Triamcinolone acetonide	12–36	Kenalog	Particles vary greatly in size; form aggregations	40–80 (ESI) 20–40 (other sites)
Betamethasone acetate/ phosphate mixture	36–72	Celestone Soluspan	Particles vary greatly in size; form aggregations but are soluble	12–18 (ESI)
Dexamethasone	36–72	Decadron	Particles 5–10 times smaller than red blood cells; can aggregate	Variable

(ESI: Epidural steroid injection).

Steroids

Glucocorticoids are the group of steroids used for the management of pain disorders. The administration of corticosteroids is to offer therapeutic benefit in painful spinal conditions.

Mechanism of Action

The potential mechanisms include the following:

1. A direct membrane-stabilizing effect
2. Phospholipase A2 activity blockade
3. An anti-inflammatory effect, with inhibition of prostaglandin synthesis
4. Blockade of neuropeptide synthesis
5. Sympathetic blockade
6. Interruption of nociceptive input from somatic nerves
7. Blockade of C-fiber activity in the DRG
8. The mechanical effect of the injectant breaking up epidural adhesions.

The commonly used corticosteroid preparations are highlighted in Table 7.1.

The effectiveness of the corticosteroid depends upon its solubility, and the complications associated are dependent on particle size and the preservatives used. The question of neurotoxicity of the steroids arises from the vehicle polyethylene glycol and the preservative benzyl alcohol in the steroid preparation.²⁰ Other vehicles or preservatives in the steroids that can cause potential problems are methylparaben and sodium bisulfite.²⁰

Particulate versus

Nonparticulate Steroids

A particulate steroid is considered to be more effective than a nonparticulate one for spinal injections probably because of its local accumulative nature.²¹ However, particulate corticosteroids have a risk of embolic infarct, which can result in serious neurologic consequences or death.^{22–24}

Methylprednisolone, compounded betamethasone, and triamcinolone are particulates in nature, whereas betamethasone sodium phosphate is the only injectable steroid in pure liquid form and contains no particles apart from dexamethasone, but it is short-acting. The plausible explanation for the short duration of action is that soluble steroids are rapidly cleared from the spinal canal. Paul Dreyfuss et al.²⁵ in their study found that the effectiveness of dexamethasone was slightly lesser than that of triamcinolone, but the difference was neither statistically nor clinically significant.

In epidural steroid injections, the steroids are usually diluted with LAs and/or saline to decrease the concentration of benzyl alcohol and polyethylene glycol and to improve the spread of the drug. Benzon et al.²⁰ found that dilution did not decrease the size of the particles except in compounded betamethasone, in which increasing dilutions with the local anesthetic decreased the proportion of the larger particles. According to them, commercial betamethasone is the recommended preparation if a nonsoluble steroid is preferred. Similarly, Lee et al. also concluded that despite the potentially serious complications of particulate

steroids, such as embolic infarct, it is reasonable to use dexamethasone for cervical selective nerve root block (SNRB).²² Dexamethasone is a non-particulate steroid, but its routine use awaits further studies on its safety and efficacy.²⁰

Triamcinolone, on the other hand, has a smaller percentage of larger particles than methylprednisolone and compounded betamethasone and can be used if commercial betamethasone is not available. Triamcinolone has been considered superior to dexamethasone in various other studies.²¹ The authors also prefer using triamcinolone acetone for spinal injections.

Since the systemic effects of corticosteroids may persist for up to 2 weeks, repeat injections are advocated at least 2 weeks apart.

Local Anesthetic Medications

Two of the most commonly used local anesthetic (LA) agents in spinal injections are lidocaine and bupivacaine. Their mechanism of action is through dampening of C-fiber activity, and interruption of the nociceptive input and reflex mechanisms of the afferent limb of local pain fibers, thereby interrupting the pain-spasm cycle.⁵ Some investigators even suggest that these work on free glutamate released by herniated disc material.^{6,26} Several investigators have reported on the anti-inflammatory effect of local anesthetics, which is by inhibiting phagocytosis, decreasing phagocytic oxygen consumption, reducing polymorphonuclear leukocyte lysosomal enzyme release, and diminishing superoxide anion production.⁶ Local anesthetic agents may also reduce neural dysfunction in injured nerve roots.

The clinical action of LA is described in terms of potency, speed, and duration of action. The “potency” is related to their lipid solubility; hence the more lipophilic the LA agent, the more readily it permeates the neuronal membrane resulting in higher potency. Bupivacaine is nine times more potent than lidocaine. The “speed of onset” depends upon the dissociation constant and the pH of the local tissue. Lidocaine has greater speed of onset when compared to bupivacaine. The “duration of action” is dependent upon the site of injection, the presence of a vasoconstrictor, the lipid solubility, and the dose of LA. The more vascular the location the more rapidly the agent is absorbed, metabolized, and excreted. The duration of action of bupivacaine is twice as much as lidocaine for the same dose injected. The main features of the commonly used LA are summarized in Table 7.2

Table 7.2: Main features of the commonly used local anesthetics.

Agent	Available concentrations (%)	Onset	Duration (h)
Lidocaine	0.5, 1, 1.5, 2, 5	Fast	1–2
Bupivacaine	0.25, 0.5, 0.75	Slow	2–4

Adverse reaction related to LA is rare but grave, and hence clinical vigilance must be exercised. The adverse reactions are central nervous system or cardiovascular system toxicity apart from major allergic reactions.

TYPES OF NEEDLE AND NEEDLE MANIPULATION TECHNIQUE

In general, the needles used for spinal injections are straight with a beveled tip. All these needles are styled with an outer cannula that can be used to deliver medication or to accept a smaller diameter needle in a coaxial fashion. The common size of the outer needle is 0.9 mm (22G) and the inner needle, if used, is 0.45 mm (24G). The bevel in the needle facilitates directional needle placement—the needle tip tends to go in a direction slightly away from the bevel. The notch on the needle is on the same side as the bevel of the needle tip.²⁷ One can introduce a bend or bow on the needle shaft in order to increase the deflection of the needle when it is advanced for its placement. Minor deflection of the needle can be achieved by introducing a gentle bend in the distal part of the needle.²⁸ Regardless of the method of needle manipulation used, proper holding of the needle is critical in directing the needle to its intended target.²⁷

DIAGNOSTIC SPINAL INTERVENTIONS

Discography

Discography is an investigator-dependant diagnostic tool used for localizing the pain source. It is usually undertaken when surgical intervention is contemplated to localize the “pain generator.” The source of pain is apparent in pathologies such as infection, tumor, deformity, or instability; otherwise, there is an assumption that it is the anatomic structures leading to significant clinical axial pain. The speculations are further compounded by social and emotional characterization of pain.

Discography is performed after other imaging modalities such as radiography and MRI are exhausted and

they fail to localize the patient's symptoms. Provocative discography involves injection of a contrast agent into the nucleus pulposus of the disc in question, under fluoroscopic guidance. The results of the procedure are determined by assessing the patient's response to the contrast injection.

The term "discography" used to describe the study implies a strictly anatomic evaluation. However, there are several different components to provocative discography as commonly used in practice. For instance, the internal structure of the intervertebral disc may be evaluated by static and dynamic imaging studies during and after injection. The other key feature of the study is the assessment of pain provocation. The patient's subjective response to the injection of contrast into the disc is noted.²⁹

There are four important pieces of information obtained in an appropriately performed discography: the subjective pain response, the volume and/or pressure of the fluid injected into the disc (a normal disc accepts 0.5–2.5 cc), the morphology of the disc injected, and the lack of a pain response in the adjacent controlled disc levels tested.³⁰

Indications and Contraindications

Indications: The most common use of discography is to determine whether degeneration within a disc seen on imaging studies is the primary clinically significant source of a patient's low back pain illness.³¹ Indications^{32,33} for discography include, but are not limited to, the following:

1. To evaluate whether demonstrably abnormal discs correlate with the clinical symptoms
2. To assess patients with persistent, severe symptoms in whom other diagnostic tests have failed to reveal clear confirmation of a suspected disc as the source of pain
3. To consider patients who have failed to respond to surgical intervention so as to determine pseudarthrosis or possible recurrent disc pathology
4. To assess candidates for minimally invasive surgical intervention to confirm a contained disc herniation or to investigate the dye distribution pattern before chemonucleolysis or percutaneous procedures.

Contraindications: Contraindications^{32,34} to discography include, but are not limited to, the following:

1. Coagulopathy (international normalized ratio >1.5 or platelets <50,000/mm³)
2. Pregnancy (because of teratogenic effects of radiation)

3. Systemic infection or skin infection over the puncture site
4. Severe allergy to any component of the injection mixture (injectate) or other medication
5. A previously operated disc, which may yield a false-negative or false-positive result (and thus its evaluation may be difficult)
6. A solid bone fusion that does not allow access to the disc
7. Significant compression of the spinal cord at the level to be operated
8. Facetogenic, neoplastic, inflammatory, and traumatic pain has to be excluded before discography.

Protocol of Diagnostic Provocative Discography

The following protocols are suggested when provocative discography is contemplated.

Evaluation of the patient's symptoms: The levels at which discography is performed are based on the history provided by the patient with regard to the intensity of pain (visual analog scale scores), distribution and location of back or neck pain with associated appendicular pain, clinical examination, and imaging findings.

Technique of provocative lumbar discography

Position: We prefer the prone position as it allows better visualization of the lumbosacral junction. Fluoroscopy must be positioned with a cephalad tilt to allow end on visualization of the end plates. Thus, the disc space and the angle of entry into the disc can be clearly seen. At the lumbosacral junction, the C-arm may need to be tilted up to 45° for adequate visualization of the disc space.

Anesthesia: The procedure is carried out under adequate local anesthesia and minimal sedation. Adequate local anesthesia is necessary so that the patient is cooperative during the procedure, whereas minimal sedation ensures that he or she is conscious and coherent to answer questions about pain.

The back is painted with povidone iodine and draped. Lignocaine (2%) is infiltrated into the skin, the subcutaneous tissue, and the underlying musculature.

Contrast agent: We prefer Omnipaque 350 (GE Healthcare, Cork, Ireland), which is a low-osmolar, nonionic contrast agent for discography.

Fig. 7.4: Discography images for L4–L5, L5–S1.

Approach: For lumbar spine, the entry point is located by measuring approximately four fingers' breadth distance from either side of the midline at the desired disc level using fluoroscopic guidance. A coaxial two-needle oblique extradural approach is used. First, a 0.9-mm (22G) \times 125-mm needle is introduced at about 45° to the horizon. It is targeted to enter the disc lateral to the superior articular pillar (SAP), yet medial to the exiting nerve root. Once the tip of this needle is just hitched to the annulus, a longer needle with a smaller diameter—0.45 mm (25G) \times 150 mm—is railroaded through the first needle and inserted into the nucleus of the disc.

A thicker (0.9-mm), first needle is preferred as it provides stability and a steady path toward the disc. The tip of this 0.9-mm needle stops just at the outer layer of the annulus. Thereafter, a thinner (0.45-mm) and longer second needle is railroaded through the outer needle into the nucleus of the disc. A thinner needle causes less damage and is associated with a lower risk of triggering a degenerative response in the nucleus of the disc.

Placement of the tip of the needle in the center of the disc is confirmed under the C-arm to ensure that the injection of the contrast would not be into the annulus. The contrast agent is injected into the nucleus of the disc slowly, depending upon the resistance (Fig. 7.4). Distribution of the contrast agent within the disc is assessed under the C-arm to determine the disc morphology (Table 7.3) as follows.^{34,35}

Technique of provocative thoracic discography: Thoracic discography is not a commonly performed procedure. When indicated, it is performed with the patient

Table 7.3: Six types of discogram and stages of disc degeneration.³⁵

Imaging finding	Significance
1. Cotton ball	No degeneration, soft amorphous nucleus
2. Lobular	Mature disc with nucleus starting to coalesce into fibrous lumps
3. Irregular	Degenerated disc with fissures and rents in the nucleus and inner annulus
4. Fissured	Degenerated disc with radial fissures leading to the outer edge of the annulus
5. Ruptured	Disc has a complete radial fissure that allows injected fluid to escape. This can be at any stage of degeneration
6. End plate fracture	Disruption of end plate

in a prone position. Although the technique is not very different from lumbar discography, anatomical differences between the thoracic and lumbar spines must be borne in mind. Facet joint orientation varies with different levels of the spine. In the thoracic spine, the processes face posteriorly, whereas in the lumbar spine they face medially. For thoracic discography, the tip of the needle is aimed to a radiolucent rectangular space between the SAP and the costovertebral junctions under C-arm guidance.³⁴ This avoids contact with the thecal sac, pleura, or the spinal cord. Once the position of the needle is confirmed to be in the center of the disc, the contrast agent is injected.³⁶

Technique of provocative cervical discography: With the patient in the supine position, an anterolateral approach for cervical discography is used. The soft tissues on the right side of the neck and vascular structures are manually displaced laterally, whereas the esophagus and trachea are deviated medially. The carotid pulse is palpated. Under C-arm guidance, the discography needle is inserted between these structures via a right anterior oblique approach into the central part of the nucleus. Precaution to avoid carotid puncture must be taken.³⁴ After satisfactory placement of the needle into the desired disc space, the contrast agent is injected.

Pressure-controlled Manometric Discography

Manometry may be performed during discography to determine the opening pressure, pressure at the onset of pain, and maximum pressure. Opening pressure is noted when the dye is visualized in the disc space. The injection of

the contrast agent is continued into the disc until reaching 90 psi or until pain is elicited. If pain is elicited at pressures <15 psi, the disc is considered to be chemically sensitive. A chemically sensitive disc is highly sensitive, which does not require increased pressure to provoke pain. If pain is elicited between 15 and 50 psi, the disc is considered to be mechanically sensitive. If pain is elicited between 51 and 90 psi, other sources of pain must be looked into. If no pain is provoked by 90 psi, the disc is considered to be negative. With the use of pressure-controlled manometric discography, improved and more specific diagnostic categorization of positive discography results is possible. Precise prospective categorization of positive discographic diagnoses may predict outcomes from treatment, surgical or otherwise, thereby greatly facilitating therapeutic decision making.^{37,38} Rapid injection of the contrast media may result in discrepancy between the real intradiscal pressure and the manometric pressure.³⁹ Automated pressure-controlled discography systems help inject contrast at a slow and constant rate. It is believed that automated discography helps validate the contents of discography and contributes to accurate interpretation of discography results. In addition, it may lower false-positive or negative responses compared to conventional discography.⁴⁰

CT Discography

If computed tomographic (CT) discography is contemplated, CT must be performed immediately after discography. It helps further assess annular degeneration and disruption.

Rate of False-Positives in Discography

In a study on 26 subjects with no low back symptoms, Carragee et al.⁴¹ found that the rate of false-positive discography may be low in subjects with normal psychometric profiles and without chronic pain. However, significantly painful injections were very common in subjects with annular disruption and chronic pain or abnormal psychometric testing.⁴¹ Patients with significant comorbid psychological conditions and/or secondary gain issues should not be subjected to discography due to ample evidence of false-positive findings in these patients.³⁴

However, in a systematic review of lumbar provocative discography in asymptomatic subjects with a meta-analysis of false-positive rates, Wolfer et al. obtained a specificity of 0.94 (95% confidence interval, 0.89–0.98) and a

false-positive rate of 6%. They concluded that contrary to recently published studies, discography has a low false-positive rate for the diagnosis of discogenic pain.⁴²

The patient's response to the contrast injection is assessed by asking the following questions:

- Is there pain? Feeling of sensation of pressure after the contrast injection does not equate to pain.
- What is the nature of pain? Is it similar to the kind of back pain you usually have?
- What is the distribution of pain? Does the provoked pain cover the same area as the usual pain (concordant) or a different one (discordant)?
- What is the intensity of pain on the visual analog scale?

The result is considered positive if the provoked pain is concordant, similar in nature to the usual pain and $\geq 6/10$ in intensity. The results may be compared against a control disc (morphologically normal disc on MRI). We prefer injecting the control disc before injecting the disc level in question. However, it is important that the patient is not aware of the level injected, the volume injected, and the moment of injection in order to improve the validity of the pain response. Nonpainful discs with positive imaging findings are not considered significant.

Complications

Many of the serious complications and high complication rates reported previously have decreased because of improvement in injection technique, imaging, and contrast materials.³³ Discitis is a serious complication after discography. Strict aseptic precautions during the procedure and the use of two-needle technique help reduce the incidence of discitis.^{33,43} The role of prophylactic antibiotics in prevention of discitis is controversial. Although it was previously believed that prophylactic antibiotics help reduce the incidence of discitis,^{44,45} Willems et al.⁴⁶ concluded that the risk of discitis after two-needle discography is minimal and does not justify their routine use.

Sometimes, the discography needle may brush past a nerve root, causing pain that may last for a few days. Other complications include transient exacerbation of pain and rarely, an epidural abscess. Quadriplegia and carotid artery injury are potential risks associated with cervical discography.

It was previously thought that discography may put the disc at risk of premature degeneration. However, in a study of roentgenographic changes in 188 patients at follow-up evaluations of 10–20 years, Flanagan and Chung⁴⁷

concluded that discography did not cause degenerative changes in the disc. In contrast, in a prospective, 10-year, matched cohort study, Carragee et al.⁴⁸ concluded that modern discography techniques even with the use of a small-gauge needle and limited pressurization resulted in accelerated disc degeneration, disc herniation, loss of disc height and signal, and the development of reactive end plate changes, compared with matched controls. A careful consideration of risks and benefits should be used in recommending procedures involving disc injection.

According to Boswell et al.,⁵ the evidence for cervical and thoracic discography is limited. The evidence for lumbar discography is strong for discogenic pain provided that lumbar discography is performed based on the history, physical examination, imaging data, and analysis of other precision diagnostic techniques.

■ DIAGNOSTIC AND THERAPEUTIC SPINAL INTERVENTIONS

Facet Joint Injection and Medial Branch Block

Diagnostic blocks of a facet or zygapophyseal joint can be performed by anesthetizing the joint by injections of local anesthetic/steroid intra-articularly or on the medial branches of the dorsal rami that innervate the joint, to evaluate whether the facet joint is the source of pain.⁵

The C2–3 and C5–6 facet joints are the most commonly affected segments in cases of cervical facet-mediated pain diagnosed by facet joint blocks.⁴⁹ Similarly, L4–L5 and L5–S1 are more commonly attributed to have lumbar facet pain. Pain from facets is characteristically unilateral, in the cervical spine radiating from the occiput to the nape of neck, shoulder blade, and upper back region whereas in the lumbar spine it may radiate into the buttocks up to the posterior thigh.

*Technique*⁵⁰

The patient is placed prone on the fluoroscopy table, with a pillow under the abdomen to reduce the lumbar lordosis. The overlying skin is prepared and the C-arm is rotated until the facet joint space is first seen. This renders the beam parallel to the posterolateral part of the joint, which is accessible for direct puncture. A 22-gauge spinal needle (3½ or 5 inches) is placed on the skin so that the tip is projected over the inferior part of the joint. Using the

needle tip as a marker, 5–10 mL of 1% lignocaine is injected into the skin and subcutaneous tissue. Care is taken to keep the hypodermic needle and syringe parallel to the X-ray beam. The syringe is disengaged, leaving the needle to act as a guide for the entry point and direction of the spinal needle. The latter is then introduced parallel and as close as possible to the hypodermic needle, aiming at the inferior recess of the joint, until passage through the capsule is felt and a bony end point is reached. In case technical difficulty of entering the joint is encountered, the superior recess of the joint is the second preferred site for needle insertion. Joint entry is confirmed by instillation of 0.1–0.2 mL of the nonionic contrast agent (Omnipaque), which collects in the superior and inferior recesses of the joint, giving a characteristic appearance of a seahorse on the fluoroscopy image (“seahorse sign”). Subsequently, 2 mL of 0.5% bupivacaine is injected for diagnostic purposes or 1 mL of 0.5% bupivacaine and 1 mL of triamcinolone for therapeutic purposes.⁵⁰

Intra-articular Blocks versus “Medial Branch Blocks”

Intra-articular injections are often more difficult and time consuming than medial branch blocks (MBBs) because they require access to the joint space, which may be extremely difficult or impossible in a degenerated facet joint, and care has to be taken that injection does not rupture or overly distend the joint.^{6,51} The medial branch block, in contrast, requires anesthetizing both of the medial branches that innervate the target joint.⁵ Significant leakage of intra-articular injected fluid into the epidural space and spillage over to the nerve roots have been described, which reduces the diagnostic accuracy of facet blocks. With appropriate care, this spillage is minimized with the MBB improving its precision. Finally, intra-articular blocks are appropriate if intra-articular therapy is proposed, but if radiofrequency therapy is proposed, MBBs become the diagnostic procedure of choice.⁵

The diagnostic and therapeutic results between the two techniques (i.e. intra-articular vs MBB) have been comparable,⁵² and both are associated with significant rates of false-positives and negatives.⁵³ The false-negative response rate of MBBs has been reported to be 11%.⁵⁴ Although diagnostic blocks are associated with a false-positive rate reported to vary between 25% and 45%, most investigators believe that a positive response of at least 50% improvement in clinical symptoms should be documented compared to prediagnostic MBB.^{55–57} Other investigators prefer a response of at least 80% improvement.^{58–61}

Facet Denervation

Facet denervation is a procedure by which a discrete lesion is created on the medial branches of the dorsal rami that innervate a facet joint. Although techniques such as cryoneurolysis and laser denervation have been performed, radiofrequency thermal-mediated ablation of the medial branch is the mainstay of facet denervation techniques.⁶

A major source of controversy is whether to perform confirmatory blocks before lumbar facet joint denervation. All the guidelines and commissioned position papers endorsed by major spine and interventional pain societies recommend using double blocks to screen patients for facet joint denervation. On the other hand, Cohen et al. in a multicenter analysis concluded that the degree of pain relief obtained after diagnostic screening blocks does not correlate with zygapophyseal joint denervation outcomes.⁶²

Epidural Steroid Injections

Direct epidural injection of corticosteroids for the treatment of cervical and lumbar spinal pain syndromes was first described in 1952.⁶³ The mechanism by which epidural steroid injection works is uncertain. The likely explanation for the action is the volume of injectate aids in lysis of adhesions and/or clears inflammatory exudates from the target neural structures by dilution.⁶ Three different routes used for delivery of medications to the epidural space are as follows:

1. Caudal
2. Interlaminar
3. Transforaminal.

Caudal

Caudal epidurals are considered as the safest and easiest, with minimal risk of inadvertent dural puncture, even though requiring relatively higher volumes of drugs.^{4,64} In the past, caudal epidural injections have been shown to be effective when compared with interlaminar epidural injections.^{4,65,66} However, the recent literature has shown that caudal epidural injections may not be superior to either interlaminar or transforaminal, but they may provide equal effectiveness.^{4,65,67}

Interlaminar

The interlaminar approach involves insertion of the epidural needle midway between the laminae of adjacent vertebrae.

The drug through the interlaminar route is often deposited on the dorsal aspect of the cord/thecal sac. It is conjectured that dorsal deposition of the drug may not reach the pain source that is usually located ventral to the thecal sac.

Transforaminal

Transforaminal route may be more effective than interlaminar or caudal techniques, possibly because of a higher incidence of steroid placement in the ventral epidural space.⁶⁸

Although SNRBs and transforaminal injections are often used interchangeably, purists insist on describing these as separate and distinct techniques.⁶ In the transforaminal injection, needle placement is more inferior to the nerve root and medial as compared to nerve root blocks.

Efficacy of SNRBs is also dependent on the type of pathology causing spinal radicular pain. Strobel and colleagues⁶⁹ found that patients with cervical foraminal disc herniation and resultant foraminal compromise had better pain relief than those with superimposed spinal stenosis. Similar findings were seen in selective nerve root injections in the lumbar spine for radicular pain caused by disc herniation versus spinal stenosis.⁷⁰ Lutz and colleagues found that patients with moderate to severe lateral recess stenosis responded less favorably to selective nerve root injections and were more likely to require subsequent surgery.⁷¹ In a systemic review, Manchikanti et al.⁷² concluded that the evidence is good for the treatment of radiculitis secondary to disc herniation with local anesthetics and steroids and fair with local anesthetics only; it is fair for radiculitis secondary to spinal stenosis with local anesthetics and steroids. For epidural steroid injection, Chou et al.⁷³ found fair evidence of moderate benefit compared with placebo injection for short-term pain relief in patients with radiculopathy.

Selective Nerve Root Block

Neck/back pain with radicular symptoms is due to nerve dysfunction, which can result from mechanical compression either by prolapsed disc/an osteophyte or by nerve root inflammation with numerous proinflammatory cytokines implicated in causing chemical irritation, “chemical radiculitis,” including phospholipase A2, metalloproteinases, interleukin-6, prostaglandin E2, and tumor necrosis factor.^{5,16}

Diagnostic Nerve Root Block

The value of diagnostic SNRBs in the preoperative evaluation of patients with negative or inconclusive imaging

Figs. 7.5A and B: Diagrammatic presentation of “safe triangle” or “Kambin triangle.”

studies and clinical findings of root irritation was reported in 1971 by Macnab.⁷⁴

Diagnostic selective nerve block is typically performed in a patient with persistent pain when history, examination, imaging, and other precision diagnostic injections and electrophysiologic testing do not identify the pain generator. The reported sensitivity of a diagnostic SNRB ranges from 45% to 100%.⁵ There is limited evidence on the effectiveness of selective nerve root injections as a diagnostic tool for spinal pain.⁷⁵ A variety of names have been given to this procedure: SNRB, selective nerve root sleeve injection, selective epidural, selective spinal nerve block, selective ventral ramus block, and periradicular injection.

“Safe triangle” or “Kambin triangle” (Figs. 7.5A and B): Kambin triangle is defined as a right triangle over the dorsolateral disc. The hypotenuse is the exiting nerve root, the base (width) is the superior border of the caudal vertebra, and the height is the dura/traversing nerve root.⁷⁶

Indications:⁷⁷ Indications for periradicular spinal injections include, but are not limited to, the following:

1. Patients with known cause for pain who benefit by temporary pain relief (e.g. disc prolapse, foraminal stenosis, and degenerative disc disease with nerve root irritation)
2. Patients with multilevel imaging abnormalities, to more accurately defining the levels for possible surgery (i.e. for surgical planning)
3. Patients with equivocal neurologic examination

4. Patients with symptoms but minimal or no definitive imaging findings
5. Postoperative patients with unexplainable or complex recurrent pain.

Contraindications:⁷⁷ Contraindications for periradicular spinal injections include, but are not limited to, the following:

1. Coagulopathy (international normalized ratio >1.5 or platelets <50,000/mm³)
2. Pregnancy (because of teratogenic effects of radiation)
3. Systemic infection or skin infection over the puncture site
4. Severe allergy to any component of the injection mixture (injectate) or other medication
5. The patient received the maximum amount of steroids allowed for a given period unless the injection is performed without steroids
6. A solid bone fusion that does not allow access to the nerve root foramen
7. Significant compression of the spinal cord (thoracic and cervical region) at the level to be injected.

We hereby describe the procedure of fluoroscopic-guided periradicular injections for the lumbar, cervical, and thoracic spines (Table 7.4).

Medication:⁶ Diagnostic injectate is bupivacaine hydrochloride 0.25% 0.5–1 mL and therapeutic injectate is a combination of bupivacaine hydrochloride 0.25% 0.5–1 mL and triamcinolone acetonide 1 mL (40 mg/mL).

Table 7.4: Equipment required for fluoroscopic-guided periradicular injections for lumbar, cervical, and thoracic regions.

<i>Equipment/supplies</i>	<i>Details and specifications</i>
Spinal needle (Steriseal–Unomedical, UK)	22G, 5.0 inches (lumbar) 22G, 3.5 inches (thoracic and cervical)
Spinal needle (Steriseal–Unomedical, UK)	25G, 6.0 inches (lumbar) 25G, 4.0 inches (thoracic and cervical)
Syringe 5.0 mL	Containing injectate (local anesthetic and steroid)
Syringe 2.5 mL	Containing noniodinated myelographic contrast medium (Omnipaque 350° GE Health- care, Cork, Ireland)
Syringe 10 mL	With 23G 1.5-inch needle containing 10 mL of 1% ligno- caine for local anesthesia for skin infiltration
Miscellaneous	Sterile gauze, povidone-iodine scrub, alcohol scrub, sterile towel and drapes, lead apron, C-arm (Phillips BV Libra or Siemens Arcadis Orbic)

Preprocedural assessment: Allergy to the contrast agent must be evaluated by the clinician. In cases of severe iodine contrast allergy, gadolinium and saline have been suggested as options.³⁴ Renal impairment has also to be taken into consideration before the administration of contrast agents. It is still possible to perform the procedure without intravenous contrast medium enhancement, but it is more difficult. Analgesic and anti-inflammatory medications must be stopped on the day of the procedure to avoid any likely interference to the perception of pain during the procedure. Informed consent must be obtained.

Lumbar Periradicular Injection

Patient position: We prefer the prone position as it allows better visualization of the lumbosacral junction and there is no need for any side supports or restraints to support the patient during the procedure. The fluoroscopic C-arm must be positioned with a cephalad tilt to allow end-on visualization of the end plates and pedicles at the level where the injection is to be carried out. At the lumbosacral junction, the fluoroscopic C-arm may need to be tilted up to 45°

for adequate visualization of the disc space. The patient's lower back is prepared and draped in a sterile fashion.

Approach for L1 to L4 SNRBs: For the lumbar spine, the entry point is located by measuring approximately four fingers' breadth distance from either side of the midline at the desired disc level using fluoroscopic C-arm guidance taking images in the anteroposterior and lateral plane. A coaxial two-needle, oblique extradural approach is used. First, a 0.9-mm × 125-mm needle is introduced at about 45° to the horizon. It is targeted to reach dorsal to the nerve root or in the axilla of the nerve root depending on the requirement. For lumbar nerve roots L3 and L4, the needle is advanced to a point just inferolateral to the pedicle until radicular pain is elicited. For L1 and L2 (and T9 to T12), the needle is positioned more inferior and lateral in relation to the pedicle (in the inferior neural foramen) to decrease the risk of injury to the artery of Adamkiewicz. Often, the needle must be passed until it makes contact with the vertebral body. If radicular pain is not elicited, the needle is repositioned a few millimeters away until radicular pain is reported. Once the tip of this needle is just proximal to the site of the desired position, a smaller-diameter longer needle (0.45 mm × 150 mm) is railroaded through the first needle such that it emerges in a suitably close position to the nerve root. A thicker (0.9-mm) first needle is preferred as it provides stability and a steady path toward the spinal column. Thereafter, a thinner (0.45 mm) and longer second needle is railroaded through the outer needle in the periradicular space. A thinner needle causes less damage and is associated with a lower risk of nerve root injury.

It is important to realize that the artery of Adamkiewicz (arteria radicularis magna) enters the spinal canal through the neural foramen near the DRG. This artery, which is the main supply to the lower two-thirds of the spinal cord, arises from a segmental artery from the aorta and enters the spinal canal anywhere from T7 to L4. The typical location of the artery of Adamkiewicz is on the left (approximately 80%) from T9 to L1. The artery usually enters in the superior or middle portion of the neural foramen, slightly ventral and superolateral to the DRG.⁷⁷ Therefore, with the lower thoracic and upper lumbar SNRBs (and particularly left-sided SNRBs at these levels), we prefer to block the nerve slightly more inferolaterally in relation to the pedicle.

Up to 1 mL of contrast is injected, and the needle position is confirmed with the help of C-arm imaging and

also by patient response. The injectate is then injected for therapeutic or diagnostic purposes.

Approach to L5 SNRBs: Patient positioning and C-arm rotation are similar to the aforementioned approach. Often the area in which the needle has to be passed is a triangular window formed by the inferior margin of the transverse process of L5, the superior articulating process of S1 and the iliac crest. However, with standard positioning, the iliac crest may completely obstruct the approach. If one is not able to achieve a position that places the superior articular facet at the midpoint of the vertebral body, one obtains the best possible angle that allows visualization of the upside-down triangle. In this case, needle insertion is performed from a lateral to medial direction to pass medial to the iliac crest with the tip of the needle projecting inferior to the pedicle. For the L5 nerve root, the needle is advanced parallel to the X-ray beam through the center of the triangle until radicular pain is achieved. If radicular pain is not elicited, the needle can be repositioned or, if necessary, the C-arm can be repositioned a few degrees in all directions. Once again, the vertebral body forms the backdrop for the triangle so that the vertebral body limits the depth of needle penetration.

Approach to S1 sacral SNRBs: The C-arm can usually maintain with a caudocranial angulation of the X-ray beam (image intensifier above the patient, obliqued toward the patient's head), so that the X-ray beam is either in the straight anteroposterior (AP) projection or with at most 5–10° of ipsilateral lateral angulation. The S1 sacral foramen is seen as a round lucency in the upper sacrum. For the S1 nerve root injection, the needle is placed until it contacts one of the bone margins of the sacral foramen. The needle is then advanced into the foramen a few millimeters until radicular pain is elicited. When the needle tip touches the nerve root, the patient generally reports intense pain in S1 distribution. If this pain is concordant with the patient's typical pain distribution, 0.5–1.0 mL of the nonionic myelographic contrast medium may be injected to confirm the needle position in the nerve root sheath (this step is optional). There is no depth indicator for sacral needle placement. Therefore, one must be careful not to pass through the foramen into the pelvis, and so it is important to monitor the needle trajectory in AP and lateral planes for S1 injections.

Assessing proper needle position for the lumbosacral levels: Regardless of the level injected, depth of the needle penetration should be evaluated periodically with lateral fluoroscopy. Intermittent gentle negative aspiration should

be performed during the injection to make sure that the needle tip has not entered a vascular structure. Injection of contrast agent is performed for several reasons:

1. It will indicate whether the needle is properly in the nerve root sleeve and not within the nerve root itself. Injection of the nerve root directly can cause severe, sustained radicular pain, which should be avoided if possible.
2. Contrast agent injection will also confirm that the needle is not positioned within a vascular structure, a situation that would remove the injectate from the injection site and negate any diagnosis or therapeutic benefit. Also, if the needle was placed within a vascular structure, a therapeutic injection with a particulate steroid could also result in vascular occlusion or thrombosis. In the case of the artery of Adamkiewicz, this could lead to spinal cord infarction.

The argument against contrast agent injection is that the patient experiences continuous radicular symptoms while the contrast agent is being injected. In practice, the time between contrast agent injection and nerve root block is relatively short.

Once proper needle position has been established, the injectate (diagnostic or therapeutic) is instilled into the nerve root sleeve. This is done slowly to minimize the amount that might flow retrograde into the epidural space, which would make the injection less specific. The needle is then removed. The patient's skin is then cleansed and an adhesive bandage is applied to the puncture site.

Cervical Periradicular Injection

Author's preferred technique¹³

Patient positioning: The patient is placed in the lateral position on the operating table, with the symptomatic side facing up. One or two pillows are placed under the head to prevent lateral flexion of the cervical spine. The neck is slightly extended and the patient is requested to depress both shoulders. This position helps to visualize the entire cervical spine in the majority of patients.

Approach: The fluoroscopic C-arm is centered on the relevant level and tilted by 20–30° in order to obtain oblique projections of the cervical spine. This would show the neural foramen end-on. A metallic ruler is placed transversely on the patient's neck, so that it projects at the upper border of the nerve root foramen of the level to be injected and parallel to the disc space. A horizontal line is drawn on the skin at

this level. A vertical line is drawn joining the posterior borders of the lateral masses of the adjacent vertebrae. Intersection of these lines gives us the entry point for the needle, which overlies the bulk of the trapezius muscle and falls in the posterior triangle of the neck.

The injection site is aseptically prepared and LA (2% lignocaine, Xylocaine, AstraZeneca, UK) is infiltrated into skin and subcutaneous tissues. For the “two-needle technique”, we use a 0.9-mm × 100-mm needle as the “outer needle” and a 0.45-mm × 125-mm needle as the “inner needle” (Steriseal-Unomedical, UK). The outer needle is well suited to negotiate the skin, deep fascia, and muscle layers without bending. The 0.9-mm needle with stylet is introduced through the entry point on the skin and directed using image guidance through the bulk of the trapezius muscle, keeping it posterior to the neurovascular bundle of the neck. The needle is advanced under image guidance until the tip of the needle is just anterolateral to the posterior border of neural foramen, without actually entering it. An AP view is also obtained at this stage. The stylet is removed and the inner needle is inserted through the lumen of the outer needle. The inner needle is advanced with caution, to enter the nerve root canal under image guidance, observing the patient’s response. In a majority of patients, radicular pain is reproduced at this point, which usually matches their clinical symptoms. Aspiration is attempted with a 5-mL syringe to ensure that the needle tip is not in any blood vessel. Up to 0.2–0.5 mL of the radio-opaque dye (Iopamidol, Niopam 200 Bracco UK Ltd) is injected through the inner needle to obtain an epidurogram, showing spread of the contrast medium along the nerve root. A hard copy of the epidurogram is printed for record. A mixture of 1 mL of long-acting steroid (40-mg triamcinolone acetonide, Kenalog-Squibb UK) and 0.5–1 mL of long-acting LA (0.25% bupivacaine, Marcaine, AstraZeneca, UK) is injected through the needle into the periradicular space. The patient is observed for 1–2 hours after the procedure and then discharged.

Pulsed Radiofrequency

At present, most studies indicate that the mechanism of action in the pulsed radiofrequency (PRF) procedure is an alteration in synaptic transmission, in a neuromodulatory-type effect.^{78,79} In general, there are two types of PRF procedures. The first category is intermittent radiofrequency procedures, such as the thermocoagulation of the medial branch. In this category, the potential contribu-

tion of PRF would probably be modest at best. Even if PRF were equally effective as thermal or conventional radiofrequency, the impetus to adopt PRF would lie in a significant reduction in complications or side effects. The second types of procedures are where continuous radiofrequency is used and it has limited indications. This includes PRF treatment for peripheral neuropathies, arthrogenic pain, painful trigger points, and PRF application of the DRG in patients with neuropathy or radiculopathy.

Chua et al.⁷⁹ in a review of randomized controlled trials (RCTs) concluded that evidence for the use of PRF to the DRG in cervical radicular pain is compelling. With regard to its lumbosacral counterpart, the use of PRF cannot be similarly advocated in view of the methodological quality of the included study. The use of PRF in lumbar facet arthropathy was found to be less effective than conventional radiofrequency thermocoagulation techniques.⁷⁹

Sacroiliac Joint Injections

Sacroiliac joint is formed by the articulation between the sacrum and the ilium. It has two parts, the inferior half to two-thirds of the true synovial lined cartilaginous joint and a fibrous articulation superiorly. The sacroiliac joint is attributed as a potential source of low back and/or buttock pain with or without lower extremity pain. The biggest challenge in coming to a diagnosis of sacroiliac pathology is identifying pain arising from sacroiliac joint and also assessing the contribution of the sacroiliac joint to the pain. Certain provocative test described may help us identify the sacroiliac source of pain.^{80–82}

The validity of sacroiliac joint block has been established by injecting small volumes of LA with contrast into the joint and determining contrast spread posteriorly into the dorsal sacral foramina, anteriorly into the lumbosacral plexus and superior recess extravasation at the sacral alar level along the fifth lumbar epidural sheath in radiographs.^{5,83} Construct validity of sacroiliac joint blocks has been established by determining the false-positive rate of single, uncontrolled, sacroiliac joint injections of 20% and 22%.^{84,85} False-positive responses may occur with extravasation of the anesthetic agent out of the joint due to defects in the joint capsule. False-negative results may occur from faulty needle placement, intravascular injection, or inability of the local anesthetic to reach the painful portion of the joint due to loculations. Several authors have shown the sacroiliac joint to be a source of pain in 10–30% of cases by a single-block¹² and 10–26.6% by a double-block paradigm.^{84,85}

The evidence is good for the diagnosis of sacroiliac joint pain utilizing controlled comparative local anesthetic blocks. The evidence for provocative testing to diagnose sacroiliac joint pain was fair. The evidence for the diagnostic accuracy of imaging is limited.⁸⁶

Technique

The patient is placed prone on the fluoroscopy table, with the hip and pelvis raised to 20–30°. This places the joint parallel to the X-ray beam, which is pointed directly down. It also exposes the synovial portion of the joint, allowing passing the needle vertically down. The varying obliquity of the joint will necessitate somewhat diverse degrees of tilt in different patients. Injecting small amount of contrast (0.2–0.5 mL) material will confirm the position of the needle. In addition, the contrast agent may have diagnostic implications by identifying abnormalities in articular contour, collections of juxta-articular fluid, or synovitis.⁸⁷

Intradiscal Electrothermal Therapy/ Radiofrequency Ablation/Nucleoplasty/ DiscFx

Intradiscal Electrothermal Therapy

Internal disc disruption, annular tear, and degenerated disc disease are a spectrum of the same disease leading to discogenic back pain. Discogenic pain is attributed to irritation of the small nerve endings within the annulus fibrosis. Heat was first used to treat discogenic low back pain in 1996, using a convection technology with a 5-cm active tip placed at the nucleo-annular junction.⁸⁸ In an intradiscal electrothermal therapy (IDET) procedure, radiofrequency energy is converted into heat in a thermal resistive coil that is percutaneously placed into the disc with fluoroscopic guidance. Heat is delivered at a specific temperature for a specific length of time to thermocoagulate the nerves.⁸⁹ Intradiscal electrothermal therapy is based on the principles of destroying these nerves, thus leading to pain relief.⁸⁹ The procedure involves the introduction of a flexible electrode into the painful disc, with the aim of coagulating the posterior annulus.

Maurer et al.⁹⁰ in a prospective study concluded that durable clinical improvements can be realized after IDET in highly selected patients with mild disc degeneration, confirmatory imaging evidence of annular disruption, and concordant pain provocation by low-pressure discography. However, Freeman et al.⁹¹ in an RCT—IDET

compared with a sham treatment (placebo)—found that although the IDET procedure appeared safe with no permanent complications, no significant change in outcome measures in either group at 6 months was observed. Chou et al. concluded that there is insufficient (poor) evidence from randomized trials (conflicting trials, sparse and lower quality data, or no randomized trials) to reliably evaluate IDET and coblation nucleoplasty.⁷³ On the other hand, recently Helm et al. in a systemic review found the evidence to be fair for IDET, using current criteria for successful outcomes.⁹²

Radiofrequency Ablation

Radiofrequency ablation provides a well-controlled spherical lesion around an electrode tip. Although radiofrequency lesioning can provide temperature sufficient to thermocoagulate nervous tissue, it is limited by the distance it can transmit heat.⁸⁹

Sometimes classified as a variant of IDET, “percutaneous intradiscal radiofrequency therapy” (PIRFT) is a procedure involving the placement of an electrode of the catheter into the intervertebral disc and applying alternating radiofrequency current. Chou et al. in a review of RCTs and systemic review found fair evidence that PIRFT thermocoagulation is not effective.⁷³

Nucleoplasty

Nucleoplasty is a minimally invasive technique that was first approved by the US Food and Drug Administration in 2000.⁹³ It aims to achieve percutaneous disc decompression through patented coblation technology, which utilizes bipolar radiofrequency energy to ablate and remove disc material, with coagulation of the adjacent residual disc tissue. There is weak evidence that nucleoplasty is effective in the treatment of radicular leg pain due to contained disc herniation. However, there is no evidence available with regard to its role in managing discogenic, axial back pain.^{73,94} However, in our center, carefully selected 30 patients with discogenic axial low back pain responded well for pain relief for initial 2 years. Cuellar et al.⁹⁵ in an observational cohort study failed to detect any morphologic improvement of disc abnormalities by MRI evaluation in patients with persistent pain, who underwent nucleoplasty. Thirty-two percent showed progressive degeneration in <1 year after nucleoplasty, a rate greater than expected by natural progression during the interval of examination.

DiscFx

DiscFx (Elliquence, LLC) system uses manual debulking of the disc, annular modulation, and nucleus ablation while keeping the procedure minimally invasive. It has four components: discography, manual discectomy, nucleus ablation, and annulus modulation. The hypothesis for the mechanism of this system is that high, specific ablation rate and targeted modulation of the annulus leads to a significant shrinkage by a minimum temperature distribution. Modulation of the dorsal annulus by the trigger flex probe results in shrinkage of the collagen, cauterization of inflamed structures, shrinkage of the annulus by 30%, and widening of the epidural space by 10%, thus resulting in improvement of blood circulation and venous congestion in the epidural space. The steerable delivery system permits targeted application in the region of the pathology. In addition this reduces the intradiscal pressure as it removes approximately 0.8 g of material out of the disc. Annulus modulation may also cause reduction in pain generated by the annular nerve fibers in degenerative disc disease. Manual removal of the disc material by a disc rongeur allows adequate nerve root decompression.

CONCLUSION

The interventional modalities discussed above for diagnostic and therapeutic procedures are more important and established ones out of an exhaustive list of procedures. These procedures are evolving and increasing numbers; hence, readers have to assess the procedures they want to apply in their practice very carefully.

ACKNOWLEDGMENT

We would like to thank Dr Aye Sandar Zaw (MBBS, MPH) for preparation of the figures and editing the document.

INTRODUCTION

Since the end of the 20th century, obesity has been identified as a global epidemic by the World Health Organization (WHO).¹ Recent estimates indicate that >1 billion people are overweight today and that >300 million are considered to be obese.² There is a general consensus about the definition of obesity: obesity is defined as a >20% greater body weight as compared with normal values, whereas morbid obesity is defined if the body mass index (BMI) exceeds 40 kg/m².^{3,4}

There is a steep rise in obesity in the western industrialized countries. For example, in the United States, the prevalence of obesity (BMI >30 kg/m²) increased from 14.5% in 1980 to 22.5% in 1994.⁵ In 2004, the statistics of the Centers for Disease Control showed that 67% of the US population was overweight and 32% obese.^{4,6} In 2005, Arterburn et al.⁷ reported that the US healthcare expenditures associated with morbid obesity were >111 billion US dollar in the year 2000.

The even more alarming finding is that these trends are not only seen in adults but also in children and adolescents.^{4,8,9} Similar observations have been made in European countries.^{8,10}

Overweight in children is associated with various musculoskeletal disorders, such as adolescent idiopathic scoliosis (AIS),^{11,12} slipped capital femoral epiphysis,^{13,14} axis disturbances in the lower extremity, or other growths disorders.¹⁵⁻¹⁷

Latest estimates of the WHO report 1.6 billion of people >15 years of age were overweight and at least 400 million of those were obese.¹⁸

In adults, the association between overweight and comorbidities, such as diabetes mellitus, hypertension, obstructive sleep apnea, cardiovascular disease, and increased mortality rates, has been described extensively.¹⁹⁻²¹ The combination of these medical disorders has been described as “metabolic syndrome.”²²⁻²⁶

OBESITY AND THE SPINE

In 1987, Heliövaara²⁷ for the first time identified an increased BMI as being an independent risk factor for herniated lumbar disc in men.

Two years later, Deyo and Bass²⁸ published the first survey, which analyzed the association between lifestyle and low back pain.²⁸ In a population of >27,000, they could show that smoking and obesity are independent risk factors for the development of low back pain. The most obese 20% of the subjects under investigation had a 1.7 times higher risk than the lowest 20% for developing low back pain. Even after controlling for age, gender, education level, exercise level, and employment status, obesity and smoking remained independent risk factors in a logistic regression analysis.

A meta-analysis of 56 articles from 65 epidemiologic studies about the association of body weight and low back pain published later could identify body weight of being only a weak risk factor for low back pain.²⁹

Other studies have shown a strong association between obesity and hospitalization for intervertebral disc disorders,³⁰ hospitalization for lumbar disc herniations,²⁷ radicular pain and neurologic signs,³¹ as well as severe lumbar disc herniation requiring surgery.³²

A population-based cross-sectional study among 63,968 adults performed in Norway ("The HUNT Study") indicated that obesity is associated with a high prevalence of low back pain.³³ A follow-up of this community-based study could also show that high levels of BMI may predispose to chronic low back pain 11 years later both in individuals with or without low back pain at baseline.³⁴

In a recently published smaller population, increased fat mass in the body composition of the study population was identified as being a risk factor for high levels of back pain intensity and disability.³⁵

There also seems to be a significant correlation between general and disease-specific functional health status and BMI. In the United States, a consortium of 26 spine centers (The National Spine Network) investigated 15,974 patients at their first visit. A total of 10,242 patients (64%) were obese [grade 1 (BMI: 25–29.9 kg/m²), $n = 5,732$; grade 2 (BMI: 30–39.9 kg/m²), $n = 3,836$; grade 3 (BMI > 40 kg/m²), $n = 561$]. The physical component summary scores of the Short Form (SF)-36 as well as the Oswestry Disability Index (ODI) were recorded. The general and disease-specific functional status was significantly worse in patients with a higher BMI.³¹ These patients also had higher pain scores and more comorbidities as compared to normally weighed patients. The spine patients who were morbidly obese (BMI > 40 kg/m²) had worse physical functioning as compared to patients with most other disease conditions.^{31,36–43}

In summary, there is strong evidence from the scientific literature that an increased BMI has a negative impact on the functional status of spine patients. Obesity may predispose for chronic low back pain and has a potentially negative influence on various (mainly degenerative) lumbar spine pathologies.

OBESITY AND OUTCOMES OF SPINE SURGERY

Surgery for Adolescent Idiopathic Scoliosis (AIS)

There is only scarce data on whether obesity acts as an independent determinant for the outcome of spinal surgery. In 2008, Upasani et al.¹⁸ investigated the influence

of obesity on the surgical outcome in AIS. In a prospective, uncontrolled study on 241 patients, who were operated for AIS, the preoperative rate of obese patients was 19.9% (48/241).

The authors could not identify a significant influence of overweight neither on clinical outcomes (self-image, function, and patient satisfaction) nor on perioperative morbidity or mortality. There was also no effect of obesity on the ability to achieve or maintain correction of the deformity. However, in the group of overweighted patients ($n = 48$), the degree of obesity was quite moderate with an average BMI of 26 kg/m² (range: 20.9–37.0 kg/m²). This might be an explanation for the lack of significant differences among the two groups.

Conclusion

In the rather young patient population suffering from idiopathic scoliosis, the prevalence of obese patients is low. No significant influence on perioperative morbidity, degree and maintenance of correction, as well as on clinical outcomes, could be identified hitherto.

Surgery for Degenerative Spinal Stenosis

In a series of 2,633 patient [46% overweighted (BMI: 25–29.9 kg/m²); 23% obese (BMI > 30 kg/m²)], who had surgery for lumbar spinal stenosis, clinical outcomes as measured with Euro-QoL Group Index and ODI were analyzed from the Swedish Spine Registry.⁴⁴ Although all patients showed a good improvement from baseline, the outcomes in obese patients after 2 years showed a significantly increased use of analgesics, more leg and back pain, an inferior quality of life, and a higher rate of dissatisfaction.⁴⁴

Two clinical studies recently described the influence of obesity on the outcomes of patients surgically treated for degenerative lumbar spinal stenosis. Within the Spine Patient Outcome Research Trial a total of 373 normally weighed patients (BMI < 30 kg/m²) versus 261 obese patients (BMI > 30 kg/m²) with degenerative lumbar spinal stenosis were identified.⁴⁵ Treatment effects (operative and nonoperative) were analyzed at a 4-year follow-up in both groups. Primary outcome measures were SF-36 bodily pain and SF-36 physical function, as well as ODI. Regardless of BMI, patients who had been operated had better outcomes at all time points as compared to those treated without operation. There was no influence of the BMI, neither on peri- or postoperative morbidity nor on complications, mortality, or primary outcome measures.

Another group of 376 non-obese versus 225 obese patients with a combination of spinal stenosis and degenerative spondylolisthesis (DS) was analyzed within the same trial. In this group as well, surgical outcome was significantly better as compared to nonoperative treatment. However, at 4-year follow-up, patients who had undergone surgery for DS had less improvement from baseline primary outcome measures. There was a significantly increased wound infection rate in the obese patients as well as two times higher reoperation rate within a 4-year follow-up.⁴⁵

Summary

There seems to be no scientific evidence for inferior outcomes or increased perioperative morbidity in patients who undergo decompression alone for lumbar spinal stenosis. However, if decompression is combined with surgical stabilization/fusion, obese patients seem to have less improvement at 4-year follow-up as well as a higher rate of wound infection and reoperations.

Obesity and Lumbar Fusion

Instrumented surgical fusion of motion segments of the lumbar spine is exposed to significantly higher biomechanical loads in obese as compared to normal weighed patients. This might influence the “healing process” of fusion, the speed of material fatigue (e.g. pedicle screws), as well as the postoperative outcome. In a retrospective analysis of 270 patients treated at a single center, Djurasovic et al.⁶ analyzed the influence of obesity on clinical outcome after lumbar fusion.

They looked at the clinical results of patients who had undergone lumbar fusion for various pathologies, such as DS, “instability” (not further specified), spinal stenosis, scoliosis (not further specified), disc pathology, nonunion, and others. They classified obese patients ($n = 109$) with having a BMI of $> 30 \text{ kg/m}^2$ versus nonobese ($n = 161$) with a BMI of $< 30 \text{ kg/m}^2$. Outcomes were measured using the ODI, SF-36 questionnaires, and Visual Analog Scale (VAS) leg and back pain pre- and 2 years postoperative.

There was a trend toward better outcomes of non-obese versus obese patients; however, the mean improvements in both groups did not show a statistically significant difference.

The overall complication rate however was significantly different with a total of 28.4% complications in the obese group versus 17.4% in the non-obese group.

The higher complication rate was mainly attributed to a higher rate of wound infections and wound healing disturbances.

Another recently published analysis of lumbar spine fusion patients focused on differences between obese (BMI $> 30 \text{ kg/m}^2$) and morbidly obese (BMI $> 35 \text{ kg/m}^2$ + significant comorbidities), the latter being considered as a high-risk group.⁴⁶ A total of 63 patients (32 obese; 31 morbidly obese) were analyzed retrospectively after having undergone a lumbar fusion operation. Fusion had been performed mainly for degenerative pathologies. The American Association of Anesthesiologists (ASA) scores were higher in the morbidly obese group indicating a generally higher surgical risk. The authors could not identify a significant difference in surgical time, blood loss, hospital stay, or the outcomes between the two groups as referred to VAS and ODI scores. However, overall complication rates of 45% (morbidly obese) and 44% (obese) were high. Interestingly, although there was a significant improvement of symptoms in both groups postoperatively, no weight loss was achieved at an average follow-up of 20.4 months.

A very recent paper published in 2012 describes the epidemiology and outcomes of lumbar fusion surgery as referred to the presence of a metabolic syndrome.²⁶ Although there are various definitions of metabolic syndrome, there seems to be a consensus that the coincidence of obesity, diabetes, hypertension, and dyslipidemia should be considered as metabolic syndrome.^{24,25} The analysis was carried out for the years 2000–2008 in a total of 238,296 patients who were identified through the National Inpatient Sample (NIS) in the United States of having been admitted to a hospital for posterior lumbar spine fusion. Interestingly, the increase of metabolic syndrome over this 8 years period was more than threefold with an average prevalence of 9% in the 2008 patient population. The outcome analysis showed significant differences between patients with or without metabolic syndrome. Length of hospital stay was longer, hospital charges were higher, nonroutine discharges were more frequent, and here was a significantly higher rate of life-threatening complications in patients with metabolic syndrome.²⁶

A retrospective cross-sectional study of spinal fusions in California from 2003 to 2007 was published by Kalanithi et al.⁴⁷ in 2012. They analyzed healthcare costs and complications in 84,607 hospital admissions. The data were taken from the Health Care Cost and Utilization Project's California State Inpatient databases. The analysis focused on patients who had undergone one of four types of spinal

fusion: anterior cervical fusion, anterior lumbar fusion, posterior cervical fusion, and posterior lumbar fusion. In-hospital complication rates were 97% higher in morbidly obese patients undergoing one of these procedures as compared to normally weighed patients (13.6% vs 6.9%). Mortality in the obese patients was higher (0.41 vs 0.13; $p < 0.01$). Average hospital costs were higher ($p < 0.0001$), as well as length of stay ($p < 0.0001$). Morbid obesity turned out to be the most significant predictor for complications in anterior cervical and posterior lumbar fusion.

Summary

Although the overall outcomes of obese patients undergoing lumbar spine fusions for various (mainly degenerative) pathologies do not seem to differ from nonobese patients, there is increasing evidence that perioperative morbidity and complication rates including life-threatening complications seem to be significantly higher in obese patients or in patients suffering from metabolic syndrome. This seems to be associated with increased overall costs.

COMPLICATIONS AND SURGICAL COMORBIDITIES IN THE OBESE PATIENTS

The analysis of currently available data shows that the complication rates of different types of spinal surgery in obese patients ranges from as low as 12.5% in young patients suffering from idiopathic scoliosis without significant comorbidities¹⁸ to up to 74.1% in the typical patient population undergoing spinal surgery for degenerative spine disorders.^{6,10,26,45-48} Whereas technical and intraoperative aspects seem to play a minor role, it can be assumed that the comorbidities are the significant drivers of these complication rates. Moreover, surgical site infections (SSIs) and wound healing disturbances ascribe for the majority of postoperative complications in obese patients.^{6,10,26,45,48} In a recently published meta-analysis on SSI after spinal surgery, only obesity, diabetes mellitus, and previous SSI could be identified as being significant risk factors.⁴⁹ The distribution of body fat seems to be more important for the development of SSI than the BMI per se. Mehta et al.⁵⁰ recently could find that, besides the number of operated levels, the skin-to-lamina-distance and the thickness of subcutaneous fat were significant risk factors for SSI, whereas BMI itself was not.⁵⁰

In any case, SSI seems to be one of the most important complications to be avoided since it is one of the top

three reasons for unplanned readmission to hospitals after spinal surgery⁵¹ and leads to a reoperation in the majority of the cases.

In most of the published papers, the prevalence of preoperative comorbidities shows a wide range between 0.9% and 100%; however, they always contribute significantly to the rates of peri- and postoperative complications, length of hospital stay, and costs.^{26,45,46}

PRACTICAL TIPS

Expectation Management

From the author's personal experience and from the available data in the scientific literature, it seems to be important to achieve a shared decision on surgery together with the patient. The majority of obese patients undergo elective surgical procedures for degenerative spine pathologies. This means that if we consider the current scientific data in complications and outcomes, an individual risk-benefit analysis is necessary for each individual case. The dialogue with the patient to achieve an informed consent must address unrealistic expectations on the patient's side. And last but not least, the influence of obesity on further degeneration of the patient's spine should be discussed.

Morbidly obese patients should not generally being denied spinal surgery; however, compliance needs to be obtained. The increased risk potential due to obesity should be openly discussed. In cases with no time pressure, patients should be motivated to first loose weight before an operation is performed. In morbidly obese patients, the author strongly recommends his patients to consult a bariatric surgeon preferably before the planned operation.

The patient must be informed specifically about all additional surgical risks, which are associated with his or her overweight. If from a surgeon's and anesthesiologist's point of view the risks overrate the expected benefits, surgery should be avoided. Do not forget that most patients do not loose weight after surgery, although they often pretend that the loss of mobility is responsible for their weight increase.⁴⁶

This might influence your surgical decision especially when spinal fusion is considered.

Technical Aspects

Patient positioning can be difficult (Fig. 8.1) to avoid pressure sores; head, arms, and knees have to be carefully protected (Figs. 8.2 to 8.4). Occasionally, positioning needs to be modified. Most obese patients have heavy heads, so

Fig. 8.1: Difficult knee-chest positioning for lumbar decompression in an obese patient.

Fig. 8.2: Risk of pressure lesion of ulnar or median nerve.

Fig. 8.3: The knees need to be supported to avoid slipping from the operating room (OR) table (Attention: Avoid pressure on the peroneal nerve).

Fig. 8.4: The head needs to be positioned without pressure on eyes, nose, and mouth.

eye protection plays an important role to avoid postoperative amaurosis or lesions around the eye (Fig. 8.5).⁵²

There are first reports, which describe potential advantages of minimally invasive approaches to the spine in obese patients.^{26,53,54} There is currently not enough scientific evidence in the literature to support the argument that complications rates and/or outcomes can be improved with the use of less invasive approaches; however, the advantages of minimally invasive spine surgery, such as less tissue trauma, small approaches, less blood loss, shorter immobilization, and shorter hospitalization, suggest a potential and special benefit of the use of these techniques in obese patients.

Careful tissue handling, avoidance of retractor pressure on skin and muscles, careful hemostasis, and all measures, which potentially avoid SSI, are important. This includes repeated wound irrigations intraoperatively, shortening of operating room (OR) times, application of local antibiotics, or prolonged infection prophylaxis perioperatively.

CONCLUSION

The beneficial effect of bariatric surgery on the spine has been analyzed recently in an interesting prospective study.⁵⁵ In a prospective series of morbidly obese patients (BMI >35 kg/m²) with low back pain, bariatric surgery was performed (laparoscopic gastric banding, sleeve

Fig. 8.5: Postoperative pressure sore around the eye after prone positioning.

gastrectomy, laparoscopic Roux-en Y gastric bypass, and duodenal switch). Average reduction of BMI was from 42.8 to 29.7 kg/m² at 1-year follow-up. Low back pain and radicular pain significantly decreased ($p < 0.001$). Moore-head-Ardelt life quality score improved significantly ($p < 0.001$). The most interesting finding however was that there was a significant increase in L4-5 disc height ($p < 0.001$) as measured pre- and 1-year postoperative with computed tomography scan.

This is the first paper, which describes a significant influence of weight loss on disc height, thus indicating a beneficial effect on the degenerating disc.

In summary, obese patients undergoing spine surgery need special attention. Their outcomes seem to be comparable with non-obese patients, however, associated with a significantly higher risk of experiencing complications (mainly wound infections and general complications). If spine surgery can be postponed, bariatric surgery is recommended before spine surgery.

If surgery cannot be postponed in morbidly obese patients, bariatric surgery should be recommended after spine surgery.⁵⁶⁻⁵⁸

KEY POINTS

- Obesity is associated with other comorbidities and increases the risk potential for spinal surgery.
- Wound infections and general complications are higher in obese patients as compared to normally weighted patients.

- Obesity predisposes for experiencing low back pain and has a negative influence on the natural course of degenerative spine pathologies.
- Morbidly obese patients for whom spinal surgery is planned should be seen by a specialists in bariatric surgery before spine surgery as part of the routine preoperative workup.
- The indication for surgery should be restrictive in obese patients, and, if surgery cannot be avoided, a strict expectation management before the operation is mandatory.

INTRODUCTION

The pathophysiology, pathoanatomy, and pathomechanics of the spine in the aging patient form the basis for the discussion of the spinal disorders seen in the elderly. Spondylosis, metabolic bone disease (specifically, osteoporosis), and tumor are seen much more commonly in the geriatric population. Spondylosis is a degenerative local process specifically affecting the spine, whereas osteoporosis and other metabolic bone diseases are systemic processes that preferentially affect the spine because it contains the largest quantity of metabolically active trabecular bone. Malignant spinal neoplasms may be categorized as either primary or secondary. Also, they may be either local or metastatic. The treatment of the elderly patient with a spinal disorder is challenging and involves numerous issues not relevant in younger patients (Table 9.1).

PHYSIOLOGIC AND PHARMACOLOGIC EFFECTS OF AGING

Basal Metabolic Rate and Temperature Regulation

The basal metabolic rate (BMR) declines 1–2% per decade from the age of 20–80 years.¹ Aging combined with a decreased level of physical activity contributes to this decrease in BMR. Shivering is less common in older patients

Table 9.1: Spinal disorders in the elderly.

<i>Disorders</i>	<i>Specific conditions</i>
Degenerative	Lumbar disc disease Back pain Radiculopathy Neurogenic claudication Cervical disc disease Neck pain Radiculopathy Myelopathy
Deformity	Degenerative spondylolisthesis Degenerative scoliosis
Trauma	Compression fractures Central cord syndrome
Tumor	Metastatic disease Primary bone tumor
Infection	Pyogenic vertebral osteomyelitis Granulomatous vertebral osteomyelitis
Inflammatory	Rheumatoid arthritis Atlantoaxial instability Basilar invagination Subaxial instability Ankylosing spondylitis

because a lower core temperature must be reached to trigger a response,² placing the elderly at greater risk of perioperative hypothermia.

Cardiovascular Function

Advancing age is associated with loss of arterial elasticity and reduced arterial compliance as elastin production declines and collagen is damaged over time, leading to an overall “stiffening” of the heart and vascular system.³ The progressive reduction in nitric oxide production with aging also contributes to vascular stiffening.⁴ As the aging heart pumps against an increased afterload, the left ventricular wall thickens, leading to ventricular hypertrophy.⁵ Although these age-related changes in cardiac function preserve systolic function, the decrease in left ventricular compliance impairs early diastolic filling, making the aging heart dependent on late diastolic filling.⁶ Because late diastolic filling is a function of atrial function, hemodynamic instability can result from the presence of supraventricular arrhythmias.⁷ Impairment in the ventricular relaxation phase, termed *diastolic dysfunction*, also predisposes the elderly patient to fluid overload and “flash” pulmonary edema.⁸

Autonomic Nervous System Function

Autonomic nervous system (ANS) function progresses from parasympathetic predominance at birth to gradually increasing sympathetic activity in early adulthood. Sympathetic activity predominates in later life as parasympathetic activity progressively declines. A concomitant decrease in β -adrenoreceptor responsiveness renders the elderly patient's ANS less capable of responding to stressful stimuli.⁵ The baroreflex likewise suffers from the age-related decrease in vagal activity, resulting in a reduced capacity to maintain a stable arterial blood pressure in response to acute physiologic changes during the perioperative period.⁹ The combination of ANS changes and structural changes in the cardiovascular system can increase blood pressure variability.⁷ The clinical consequences of autonomic aging include increased blood pressure lability, reduced responsiveness to inotropic and chronotropic drugs, and an increased dependence on preload to maintain cardiac output.

Pulmonary Changes

After the age of 50 years, lung compliance decreases secondary to loss of parenchymal elasticity, loss of chest wall compliance due to calcification of the costochondral joints, and decrease in alveolar surface area.¹⁰ These changes result in a decrease in vital capacity, expiratory flow, and diffusion capacity, and an increase in residual volume, closing capacity, dead space, and ventilation-perfusion

heterogeneity.¹⁰ Clinically, elderly patients experience gas exchange abnormalities that require progressively increasing inspired oxygen concentrations.¹¹ Older patients also have impaired respiratory responses to hypoxia and hypercapnia and an increased sensitivity to the respiratory-depressant effects of opioid analgesics and benzodiazepines.¹⁰ Advanced age is an important predictor of postoperative pulmonary complications, including aspiration, pulmonary edema, atelectasis, and pneumonia.¹²

Renal and Hepatic Effects

The kidneys lose approximately 10% of parenchymal thickness per decade of life,¹³ accompanied by a 10% decline in renal blood flow per decade, contributing to a 30–50% decrease in creatinine clearance between the age of 20 and 90 years.¹⁴ Despite this decline in renal function, serum creatinine levels remain in the normal range because the production of creatinine decreases as a result of the loss of muscle mass, which occurs at a rate similar to the decline in glomerular filtration rate. Liver mass also decreases by 20–40% during the typical human lifespan, with a concomitant decline in hepatic bloodflow.¹⁵ Impaired hepatic and renal function in elderly patients affects the metabolism and excretion of many different anesthetic, analgesic, and muscle-relaxant drugs.

Cerebral Effects

Cerebral atrophy increases and cerebral perfusion decreases after the age of 60 years, but there is marked heterogeneity in the magnitude of these changes.¹⁶ On average, there is a 15% decrease in white matter by the age of 90 years,¹⁷ which may predispose the elderly to postoperative cognitive disorders^{18–20} and increase their sensitivity to the central depressant effects of anesthetic medications. Aging results in an overall loss of neurons in both the cerebral cortex and the spinal cord and slows conduction velocity in peripheral nerves, resulting in an increased sensitivity to the local anesthetics used in neuraxial and peripheral nerve blocks.²¹ However, a cause-and-effect relationship has not been firmly established between neurodegenerative disorders and anesthesia in the elderly.²²

Effects of Aging on Pharmacologic Effects of Anesthetic Drugs

As individuals age, there is a progressive loss of skeletal muscle mass and total body water as muscle is replaced

with adipose tissue, especially in women. An increase in adipose tissue leads to an expansion of the “lipid (deep) reservoir” for centrally active anesthetic drugs [e.g. benzodiazepines, volatile agents, opioid analgesics, and sedative-hypnotics (IV anesthetics)], contributing to prolonged elimination half-life values and an increased duration of action of these drugs in the elderly.²³ In addition, the reduction in total body water decreases the central volume of distribution for water-soluble drugs, resulting in higher average and peak plasma drug concentrations and an enhanced peak (maximal) effect.¹⁴ Older patients with poor nutrition can have a 20% or more decrease in albumin levels. Because many anesthetic drugs are highly bound to albumin (e.g. propofol and diazepam), even modest decreases in albumin levels can increase free-drug concentrations, contributing to increased sensitivity to these drugs in the elderly.

Although oral drug absorption from the gastrointestinal tract is often delayed in the elderly, these changes are of minimal importance in the perioperative setting because the majority of anesthetic and analgesic medications are administered intravenously. Age-related pharmacokinetic changes in drug distribution, metabolism, and elimination have a significant impact on drug dosing in geriatric patients.^{21,23,24} The mechanisms responsible for the pharmacodynamic changes associated with aging are less well understood. However, the aging of the central nervous system results in neuronal loss and a decline in cognitive reserve, contributing to the enhanced sensitivity of the elderly to centrally active anesthetic drugs. As a result of these age-related changes, the central nervous system depressant effects of anesthetic drugs (e.g. sedation, hypnosis, and cardiorespiratory depression) occur at lower blood and effect-site concentrations in older patients.²² The old adage to “start low and go slow” applies when administering potent anesthetic and analgesic drugs to elderly patients in the ambulatory setting.

Drug Interactions in the Perioperative Period

Polypharmacy, the term used to describe the use of multiple chronic medications, is common among elderly patients undergoing ambulatory surgery procedures. It is estimated that 40% of geriatric patients take five or more different drugs per week, and 12–19% use 10 or more drugs in a week.²⁵ An expert panel found that polypharmacy (defined as five or more chronic medications) was the only patient characteristic associated with adverse drug

reactions in patients >65 years.²⁶ Combinations of analgesic medications (e.g. opioids, local anesthetics, and anti-inflammatory drugs) can produce enhanced postoperative analgesia as part of a multimodal regimen, but their interactions may contribute to delayed wound healing in the elderly.^{27,28} Anesthesia providers should be aware of all prescription, “over-the-counter,” and herbal medications taken by elderly outpatients to minimize adverse events from drug interactions in this high-risk surgical population.

PREOPERATIVE ASSESSMENT

Indication and Goals of Surgery in the Geriatric Patient

The basic indication for surgery in the elderly patient is failure of conservative treatment after a reasonable period of time. For example, pain management is the primary consideration and goal of elective foot surgery in the geriatric patient.²⁹ Severe foot pain can result in an active alert older patient becoming nonfunctional, dependent, and severely depressed.

Functional restoration enabling the individual to resume former activities of daily living (i.e. ambulation) is the second goal of surgery. An elderly patient may not be able to ambulate as a result of a particularly severe hallux valgus deformity, permitting the patient to walk again and resume activities of daily living.

Limb salvage is a critical primary goal of surgery in the older debilitated patient. Quality of life is an important consideration. The number of lower extremity amputations for diabetes and malignancies has been reduced markedly to offer the individual a higher quality remainder of life.

Review of Systems

Physiologic changes occur with normal aging even in completely healthy individuals. The major changes in the cardiovascular system seen with aging are related to stiffening and decreased distensibility of the systemic arteries and the cardiac wall. The cardiovascular system in the elderly patient usually responds less well to stress. General physiologic aging changes, such as decreased cardiac efficiency, arteriosclerotic vessel lumen narrowing with decreased tissue perfusion, and pathologic conditions, such as ischemic heart disease, hypertension, cardiac arrhythmias, and congestive heart failure, diminish the geriatric patient’s ability to respond to the stress of surgery.²⁹

Respiratory system function declines in the geriatric individual as a result of aging. With aging, the breakdown of elastin and cross-linking of collagen impair the elastic recoil of the lung. The chest wall becomes less compliant. Pulmonary circulation is reduced as a result of proliferation and fibrosis of the intimal and medial layers of the pulmonary arteries.

Renal function declines in aging with a gradual loss of renal mass. There are minimal losses of functional changes in the liver because of the presence of substantial hepatic reserve. The immune system is also diminished in the elderly. There is a decrease in cell-mediated and humoral immunities. The system that undergoes the most changes in the elderly is possibly the musculoskeletal system. The rate of bone loss following menopause may temporarily approach 3% a year in some women. Bones typically become less stiff, less strong, and more brittle with aging.

Osteoporosis occurs more frequently in the elderly. Calcium supplement perioperatively is helpful in speeding bony healing and in slowing the osteoporotic process. The geriatric patient with osteoporosis should not have base wedge surgery and postoperatively should not be casted for a long period of time.³⁰ The procedure for a patient with any degree of osteoporosis must allow for early postoperative ambulation. If a cast must be used, it should be bivalved for easy removal, or a lightweight prefabricated walking brace might be more appropriate.

Muscles become less powerful with reduction in the fast-twitch type II muscle fibers and a reduction in the number of motor units. Aging increases the amount of connective tissue, which results in decreased range of motion and increased muscle stiffness. The density of bone decreases, especially in postmenopausal women. Osteoporosis is common, also reducing the potential for postoperative healing.

Osteoarthritis is common in > 70 years. Bone, cartilage, fascia, tendons, ligaments, and joint capsules may all be severely weakened.²⁹ Osteoarthritis is most common in the elderly hip and knee and will impact postoperative healing of foot surgery.

Estimating General Risks of the Surgery and Reducing Them

The American Society of Anesthesiologists (ASA) criteria remain the best tool for estimating the overall risk of surgery. Patients are divided into five clinical categories that predict mortality in elective and emergency surgery. Class 1

Table 9.2: American Society of Anesthesiologists physical status scale and risk of surgery.

Class	Physical status
I	Normal healthy individual
II	Mild systemic disease
III	Severe nonincapacitating systemic disease
IV	Severe incapacitating systemic disease with a constant threat of life
V	Moribund patient who is not expected to survive 24 hours with or without operation
VI	Added to any class patient undergoing emergency surgery

is the normal healthy individual. The ASA scale adjusts for age by not permitting an elderly person to receive a class 1 designation. Patients >80 years by definition are at least ASA class 2. Patients with severe systems disturbances that were not life threatening (class 3) have 4% mortality rate. Patients with life-threatening physiologic derangement are class 4 and have 25% mortality rate in surgery. Patients who will not survive for 24 hours without the operation are class 5. Emergency operations are classified as “E” and double the risk.³¹ If the patient is classified in any category other than class 1 or 2, hospitalization is often advisable for even minor procedures, such as removing nails or warts, unless an anesthesiologist is available to monitor the patient in the office³⁰ (Table 9.2).

Because podiatric surgery is generally elective, the patient’s overall health should determine whether and when the surgery should be performed. Because geriatric patient with a high rate of increased concomitant diseases and suboptimal biological factors is at increased risk for surgery, the surgeon and anesthesiologist should be taken all measures to reduce the risk as much as possible. These measures include strict selection of indications for operative treatment. Because the great majority of podiatric surgery is elective, the surgery should be absolutely necessary to alleviate pain and improve function. The patient who is nonambulatory or whose ambulation is minimal should be ruled out as a candidate for elective surgery.³²

The patient’s expected lifespan must be considered. The patient must have a reasonable expectation of living long enough to benefit from the surgery. Although a 75-year-old woman can expect to live to the age of 87 years, approximately seven of her remaining years are likely to be marked by at least partial loss of functional independence.³³

There must be full preoperative preparation for the surgery, which includes clinical and psychological preparation. The most appropriate and least aggressive surgical procedure should be selected. The actual time it takes to perform the surgery is also a consideration. Lengthy procedures may expose the patient to infection, shock, atelectasis, and vascular problems. If the procedure must be lengthy, it might be best to stage the procedure rather than doing the entire procedure at once. Digital or nail surgery can be successfully performed in an office setting, but major podiatric surgery should be performed in a hospital.³² The anesthesia should be appropriate and localized if possible. A tourniquet should be used to prevent precipitating ischemic gangrene and venous damage causing thrombophlebitis. Paradoxically, not using a tourniquet may increase blood loss and even a small blood loss in the older patient can reduce output significantly. Drains should also be avoided if possible.³² The postoperative period should emphasize mobility, and the patient should spend as brief a time in bed as possible.

Choice of Anesthetic Technique

In the elderly population, it is good to minimize the length of stay in the hospital, with a quick return to their normal surroundings. For this reason, optimal choice of anesthetic technique can play a very important role in achieving this goal. For example, selection of a regional (spinal or epidural) anesthetic technique may be more desirable than general anesthesia in the elderly, where potential complications (e.g. aspiration or postanesthesia delirium) could prolong hospital stay. Good communication between the surgeon and the anesthesiologist is essential in this situation.

Local Anesthesia

Many minor urologic procedures can be done either in the office or in an outpatient setting using local anesthetics. The advantages of such a choice of anesthesia in the elderly patient include lower cost, ease of administration, and a quick return to their normal environment. Although the use of local anesthetics often is considered trivial, one must be aware of the potential complications or toxic reactions to local anesthetics if used improperly. Often the urologist administers not only the local anesthetic but also many intravenous sedatives (e.g. benzodiazepines) to supplement the local anesthesia. Knowledge of the potential adverse reactions to these sedatives and their treatment is very important, especially in the elderly population where

the response to many sedatives often is exaggerated and prolonged. Proper monitoring in this setting, including blood pressure, respiratory rate, and pulse oximetry, by qualified personnel is essential. When scheduling the patient for an office procedure that may require supplemental sedation, it is important that they are informed of the need to have someone who can drive them home after the procedure.

Regional Anesthesia

Use of regional anesthetic techniques in urologic practice, especially spinal and more recently epidural, is very popular because most procedures take place in the lower abdomen or pelvis. The advantage of this is that the pulmonary ventilation, myocardial function, and cerebral blood flow all remain unaffected.³⁴ Another important advantage of the regional technique is that the patient is allowed to remain awake during the procedure.^{34,35} This allows the anesthetist to constantly assess the patient's mental status, especially in a patient with preoperative cognitive impairment.³⁵ The patient can also make the surgeon or anesthetist aware of any potential complications (e.g. chest pain and diaphragmatic irritation) that may occur during the procedure.³⁴

Depending on the type and length of procedure performed, a single shot of either a short-acting local anesthetic (e.g. lidocaine) or longer acting agent (e.g. bupivacaine) may be selected. The anesthetist must be aware of the age-associated decrease in the quantity and change in the configuration of myelinated fibers in the dorsal and ventral roots of the spinal cord, thus requiring a reduction in the amount of local anesthetic given.³⁶ For many major urologic procedures in the elderly patient these techniques can be used for longer periods of time (i.e. continuous spinal or epidural). Even if the entire surgical procedure cannot be performed with the patient awake, the use of continuous regional anesthetic catheters allows for a reduction in the amount of general anesthetic required, which is of great importance in the elderly patient. Another advantage of the epidural catheter is that it can be used in the postoperative period with either a constant infusion or by patient-controlled analgesia (PCA), thus reducing the amount of postoperative pain and allowing for early ambulation to help prevent deep venous thrombosis.

Recently, a randomized study was undertaken by Shir et al.³⁷ on the effect of general anesthesia versus epidural anesthesia in postoperative pain and analgesic requirements in patients undergoing radical prostatectomy.

Patients were assigned randomly to receive epidural anesthesia, combined epidural and general anesthesia, or general anesthesia only. Results revealed that intraoperatively, epidural patients received significantly more epidural bupivacaine than combined epidural and general anesthesia patients. Recovery room median residual sensory level in epidural patients was significantly higher than in combined patients. The PCA demand was greater in the general anesthesia and combined groups when compared with the epidural group in the postoperative period, but there was no difference between the combined and general groups. There were no significant differences in postoperative mean pain scores in the first 5 days after surgery in the three anesthetic groups. They concluded that epidural local anesthetics were associated with decreased postoperative analgesic demands.

General Anesthesia

For many reasons, local or regional anesthesia is preferred in the elderly population; however, for many patients these techniques may not be practical or possible and a general anesthetic is required. The major disadvantage in this situation is that the patient is asleep, and the anesthesiologist must rely on various monitors [e.g. continuous electrocardiography (ECG), pulse oximetry, and blood pressure monitoring] to be aware of the status of the patient. Limiting the use of general anesthesia in elderly patients minimizes the occurrence of postoperative mental changes, which have been known to last for months or years after administration of general anesthesia.³⁸ Introduction or maintenance of general anesthesia may be done by either intravenous or inhalational anesthetics or a combination of the two. This does allow for some flexibility in adjusting anesthetic agents to fit the specific needs of the patient with many comorbid conditions.

MEDICATIONS

Thorough assessment on consumed medications by an elderly should be done before the surgery. Aspirin, clopidogrel, nonsteroids, and other antiplatelet drugs increase the risk of perioperative bleeding and, if not necessary, should be discontinued for 7–10 days. Drugs with anticholinergic effects should also be discontinued, because they could increase the risk of perioperative delirium. The use of chronic benzodiazepine agents should be taken into account and should be tapered off to minimize the risk of withdrawal effect when the patient should fast during

perioperative period. When it is not essential to manage excessive fluid volume or symptoms of lung edema in patients with congestive heart failure, discontinuation of diuretic agents for 24–48 hours before the surgery should be considered. Patients consuming antiepileptic, cardiovascular, and antihypertensive agents usually have to take the drugs in the morning before the surgery using as little water as possible. An abrupt discontinuation of β -adrenergic inhibitors and clonidine is associated with significant cardiovascular complication. Oral hypoglycemic agents usually should not be taken the night before surgery to minimize the risk of perioperative hypoglycemia. Diabetic patients receiving intermediate-acting insulin therapy usually receive half their regular dosage in the morning before the surgery, and intravenous 5% dextrose is given. Plasma glucose level >250 mg/dL after the surgery could be managed with subcutaneous insulin, or if the patient is in unstable hemodynamic state (could cause altered absorption of subcutaneous insulin) short-acting insulin infusion is given. Adrenal suppression due to chronic use of steroid should be treated with steroid, usually 100 mg of hydrocortisone every 6 hours, starting from the night before the surgery and then the dose is reduced until it reaches maintenance dose in 3–5 days in relation to the postoperative condition.

ASSESSMENT OF THE HOME AND PREOPERATIVE TEACHING

When the patient presents for a presurgical clearance, an assessment of the home environment needs to be completed by the nurse. These are extremely important questions that should be answered and addressed preoperatively for the elderly patient. The case manager or social worker should be consulted as needed. Trying to solve family issues/concerns after surgery is always more difficult.

The elderly population requires extensive preoperative teaching. Patients and their support person should be told what information they need to bring for the day of surgery. Additional preoperative teaching includes a discussion of the patient's fasting status.

Other topics for discussion during the patient's preoperative teaching include the following:

- Discuss the importance of leaving all valuables at home, thus protecting the patient and the surgical facility from theft or loss.
- Ask the patient to wear loose, comfortable clothing. Elastic waist pants and slip-on shoes work the best when elderly patients have to get dressed postoperatively.

- Discuss with the patient which medications he or she should take prior to surgery and which medicines need to be withheld.
- Carefully review any skin preparation or bowel preparation with the patient and his or her significant other.
- Take the opportunity to teach the patient how to use the incentive spirometer if indicated. Coughing and deep breathing exercises should be taught with return demonstration, and patients should be shown how to splint the area of incision during deep breathing exercises.
- Discuss pain management with the elderly patient to help dismiss any misconceptions regarding pain control. Remember, many people in this generation still fear “getting addicted.”³⁹

■ NURSING CARE IN THE OPERATING ROOM

Fluid Status

The patient’s fluid status should be frequently assessed. Dehydration is a common problem for the geriatric surgical patient, especially those who come from a long-term care facility. Patient assessment should include observing vital signs, monitoring urine output, and assessing skin turgor. The patient’s fluid and electrolyte status needs to be monitored and well managed. Cleansing enemas and the use of diuretics can place the elderly at risk for dehydration.⁴⁰ Assess the patient’s mucous membranes and skin for signs of dehydration. It is helpful if elderly patients are scheduled for surgery early in the day, so they are not NPO for any longer than necessary. For surgeries late in the day, allow the patient to have a light breakfast when possible.

Positioning

In the operating room (OR), the elderly patient requires special attention. Positioning is a priority, and extra care needs to be taken to protect the spine and back. Many elderly patients are slender and their skin is fragile. They require extra padding over bony prominences.⁴⁰ Many elderly people have osteoarthritis.

Temperature Regulation

Another major problem for the elderly in the OR can be temperature regulation. Older patients are more susceptible to hypothermia due to loss of body fat.⁴⁰ Operating

rooms are kept cool and if surgery is prolonged, the patient may lose a significant amount of body heat. The use of warming blankets can help reduce the risk for hypothermia. Cover the patient’s head when possible to avoid the loss of body heat. In addition, cover their feet with paper slippers or 100% cotton socks. Inspect the patient’s feet prior to entering the OR for any signs of infections (i.e. in-grown toenails).

■ POSTOPERATIVE NURSING CARE IN POSTANESTHESIA CARE UNIT

Postoperative care of the geriatric patient in postanesthesia care unit (PACU) is a systematic process. Airway, breathing, and circulation (ABC) is the priority in phase I PACU. All patients arriving in the PACU should be assessed for the need for supplemental oxygen, especially those who received heavy sedation or general anesthesia.⁴¹ Respiratory effort and vital signs must be closely monitored. Knowing the preoperative oxygen saturation is extremely important in the PACU. Oxygen saturations of 93–95% may be normal values for the elderly patient, especially those with existing pulmonary disease.⁴² The patient’s level of consciousness and return of protective reflexes are evaluated continuously. Muscle strength is noted, especially if muscle relaxants were used in the OR. Geriatric patients may require close cardiac monitoring because of existing cardiac disease. If the patient is diabetic, blood glucose levels should be monitored (and corrected) prior to sending the patient to the floor.⁴³ This is also true for patients who are discharged home or to an extended care facility.

Priorities and responsibilities for the nurse in the PACU are numerous. The ultimate priority in the PACU is the ABC, followed by the arousal regimen. The patient is stimulated and encouraged to take deep breaths, thus facilitating the exhalation of any remaining anesthetic agents from their lungs. The second priority for the nurse is to control pain, nausea, and vomiting. Unfortunately, one side effect of administering opioids is nausea and vomiting, thereby creating a balancing act for the nurse. Positioning and warming of the patient is the third priority. The patient is assessed for hypothermia upon arrival, which is a temperature of <96.8°F.⁴⁴ Warm blankets are applied or a forced air warming system may be used until the patient becomes normothermic. The geriatric patient usually has a lower temperature upon arrival and discharge from the PACU than younger patients.⁴⁵ The patient’s preoperative baseline temperature should be noted. If the patient’s temperature is too low, metabolism slows down and excretion of

the anesthetic agents used in the OR may be prolonged, resulting in an increased stay in the PACU.

Vital signs and ECG rhythms should be monitored closely. Many older adults have significant cardiac histories and take medications that influence their cardiac rhythm and their blood pressure. Hypotension may be prolonged in the elderly patient having spinal anesthesia.⁴⁶ The patient's fluid balance can be assessed by observing the abdomen for any signs of bladder distention and monitoring urine output. The lungs should be auscultated and pulses palpated for any indication of fluid overload. The head of the bed should be elevated as appropriate to promote lung expansion. The patient should be encouraged to cough and deep breathe. High-humidity oxygen should be used as needed.

Geriatric patients who are mechanically ventilated may need additional time to meet criteria for extubation. Monitor PaCO₂ levels and assess breath sounds for proper tube placement.⁴⁷ Provide adequate pain control with intravenous opioids, epidural pumps, and/or PCA pump to facilitate extubation. Weaning criteria is met when the patient returns to consciousness, can follow simple commands, has spontaneous respirations, and can sustain a head lift for > 5 seconds.⁴⁷ Necessary personnel and equipment should be available in case reintubation is necessary.

Pain management in the elderly is also a major nursing priority. Uncontrolled pain can lead to cardiac stress, resulting in pulmonary problems and possible myocardial infarction. When medicating the older adult, start low and go slow. Geriatric patients should be assessed preoperatively to determine whether PCA and epidural pain pumps are appropriate. Patient-controlled analgesia and epidural pain pumps may not be the best choice for pain control, depending on the patient's cognitive and physical status. When the elderly patient is placed on a PCA pump or an epidural pain pump, they require consistent and timely assessment and evaluation by the registered nurse. The goal is to progress the patient from intravenous opioids to oral medications as soon as feasible. Oral forms of opioids are often better tolerated in the elderly.⁴⁴ The use of non-steroidal anti-inflammatory drugs (NSAIDs), if not contraindicated, can help reduce the amount of narcotics required. Therefore, NSAIDs, in conjunction with narcotics, should be considered for pain control in the older adult.

Assessment is the key when caring for the postoperative geriatric patient. Vital signs should be checked upon arrival to phase II recovery or upon transfer to the general

nursing unit. The ABCs are still important. Listen to breath sounds and cardiac sounds frequently inspects the surgical site for any bleeding and evaluates all complaints of pain. Palpate peripheral pulses and be aware of the patient's intake and output. In addition to a complete nursing assessment, it is important to listen to all patient complaints and assess them in a timely manner.

POSTOPERATIVE CARE ON THE GENERAL NURSING UNIT

The focus of nursing care of the geriatric surgical patient is to prevent postoperative complications and restore the patient to optimal health. Coughing and deep breathing exercises and the use of the incentive spirometer should be encouraged. The patient should perform these exercises every hour while awake. Support hose and compression devices should be applied as indicated to help prevent the development of blood clots. All surgical patients should be out of bed as soon as possible to prevent complications of immobility (i.e. deep vein thrombosis and atelectasis). Geriatric patients should be ambulated as soon as ordered. Patients should sit on the side of the bed for a few minutes before standing or sitting up in the chair (especially if they take antihypertensive medications) due to the possibility of orthostatic hypotension. Preoperative medications are resumed as ordered and should be verified with the patient or family to be sure no medication has been overlooked.

Assess bowel sounds and start the patient on liquids as soon as indicated. Monitor the patient's bowel movements. The elderly are prone to constipation, especially after surgery, and if taking narcotics. Stool softeners may be ordered postoperatively. Safety is a real issue when caring for the elderly surgical patient. Keep the call light within reach, the side rails up, and the bed in the low position. Remember, sometimes it may take up to 48 hours after surgery for the elderly patient to fully recover from the effects of the anesthetic agents.⁴⁸ Involve family members as much as possible. If the patient has no family, try to place the patient as close to the nurses' station as possible, and have Social Services coordinate arrangements for discharge care and assistance when indicated.

Elderly patients need their rest and periods of uninterrupted sleep. Complete any healthcare treatment about 1 hour prior to sleep. If the patient needs to be aroused during the night for treatments or medications, be sure to schedule periods of sleep at least 2–3 hours in duration.

If the patient requires medication to promote sleep, use the lowest effective dose possible. Promoting comfort in the elderly is where the nurse can be extremely creative. Give analgesics as scheduled and medicate the patient prior to any major dressing changes. Provide back massages and use progressive relaxation techniques with the patient. Keep plenty of extra pillows available for positioning the patient for comfort. Because many elderly patients complain of cold feet, be sure to have the family bring in cotton socks for the patient to wear at night. For the older adult patient who may not have family present, always remember that there is no replacement for the human touch.

PERIOPERATIVE SIDE EFFECTS AND COMPLICATIONS

Major morbidity and mortality after ambulatory surgery are surprisingly rare, even in the elderly population.⁴⁹ According to Fleisher et al.,⁵⁰ in 1997, only one in every 180 patients undergoing an outpatient procedure in New York required hospitalization for inadequate pain control or complications such as bleeding, nausea and vomiting, dizziness, adverse reaction to an anesthetic drug, or an irregular heartbeat. In the same study, only 19 of 783,558 outpatients studied died, a rate of one in 41.⁵¹ Aged >65 years was one of the independent predictors of immediate hospital admission after ambulatory surgery. These data suggest that older outpatients with increasing comorbidities are at increased risk of admission to an inpatient facility after outpatient surgery.

In a large retrospective outpatient outcome study by Chung et al.,⁵² 27% of the patients were >65 years. These investigators reported a 4.0% incidence of adverse events in the OR, 9.6% in the PACU, and 7.9% in the ambulatory surgery unit. Not surprisingly, adverse cardiovascular events were more common in elderly patients with preexisting cardiovascular diseases. Adverse respiratory events in the elderly were usually associated with obesity, smoking, and asthma. In the previously mentioned study by Chung et al.,⁵² older patients were four times less likely to experience any adverse event; 10-fold less likely to complain about excessive pain, shivering, and agitation; and four-fold less likely to develop symptoms of nausea and vomiting and drowsiness in the PACU than were their younger (<65 years) counterparts. It is possible that the elderly are more tolerant of the various stimuli causing side effects such as pain, nausea, and vomiting, or perhaps they are simply more reluctant to complain to their healthcare

providers. These differences may also relate to the different types of surgery and anesthesia between the elderly and younger ambulatory surgery populations in this study. For example, younger patients were more likely to undergo gynecological and orthopedic procedures, which more frequently cause postoperative pain and require the use of opioid analgesic, a factor that can also contribute to the increased incidence of postoperative nausea and vomiting. In contrast, the elderly most commonly underwent ophthalmic procedures, which cause minimal postoperative pain. The latter explanation is supported by the results of a nationwide survey in Denmark involving older (> 65 years) versus young outpatients all undergoing inguinal hernia repair in which the postoperative complication rate was actually significantly higher in the older patients (4.5% vs 2.7%).⁵³

Surgery of the Sympathetic System: Thoracoscopic Sympathectomy

Sonia Teufack, Joshua E Heller

Snapshot

- » Surgical Procedure
- » Outcomes and Complications

INTRODUCTION

Surgery to the sympathetic nervous system was first reported in 1889; Alexander performed cervical sympathectomy for the treatment of epilepsy.¹ Over the years, several indications for sympathectomy have been explored and abandoned, namely, idiocy, goiter, glaucoma, and epilepsy.² Sympathectomy still has limited application to certain conditions such as angina pectoris, Raynaud phenomenon, and reflex sympathetic dystrophy.²

In the 1920s, Kotzareff discovered that sectioning of the sympathetic chain resulted in anhidrosis.³ This led to the introduction of sympathectomy for the treatment of hyperhidrosis and flushing. Lumbar sympathectomy for plantar hyperhidrosis became less popular due to high rates of impotence in men. The current workhorse of surgery to the sympathetic system is upper thoracic sympathectomy, adapted into an endoscopic procedure by Hughes in the 1940s and popularized by Claes and Drott in the late 1980s.⁴

ANATOMY AND PHYSIOLOGY

The sympathetic nervous system originates from the hypothalamus and consists of preganglionic cell bodies in the intermediolateral column of the spinal cord from T1 to L2/3. These neurons synapse in the paravertebral ganglia of the sympathetic chain (three cervical, 12 thoracic, and lumbar/pelvis ganglia) and chromaffin cells of the adrenal

medulla. Postganglionic neurons from the sympathetic chain primarily travel with the ventral rami of spinal nerves to target organs.

The sweat response is triggered by an increased core temperature and heightened emotional states such as anxiety and nervousness. The preoptic hypothalamus is responsible for thermoregulation and sends signals through the autonomic nervous system to the eccrine glands, which secrete serous fluid and cool the body by evaporation. Eccrine glands are distributed throughout the skin, but are more abundant in the axilla, palms of the hands, and soles of the feet.

INDICATIONS

The most common current application of sympathectomy is primary axillary and palmar hyperhidrosis. It is an idiopathic overproduction of eccrine glands that affects up to 2.8% of the general population.⁵ Hyperhidrosis can have a significant impact on the quality of life of untreated patients. It can be so severe as to cause sweat to drip off the hands and require several clothing changes per day. This can also affect professional productivity, as simple daily tasks become problematic (handling paper and tools, risk of electric shock for mechanics/electricians, typing on a computer), and result in psychosocial withdrawal and depression.

Hyperhidrosis can result from a secondary process. Patient's workup should exclude conditions such as pituitary and thyroid disease, diabetes mellitus, menopause,

pheochromocytoma, spinal cord injury, certain drugs, and tumors. Important diagnostic criteria of primary focal idiopathic hyperhidrosis include focal, visible, excessive sweating for at least 6 months without secondary cause that include a minimum of two of the following characteristics: positive family history, onset before 25-year-old, frequency of at least once a week, bilateral symmetric perspiration that impairs daily activities, perspiration is absent during sleep.⁶

The first line of treatment is medical, with the use of antiperspirants, anticholinergics, and beta-blockers agents. Botox injection can provide symptomatic relief for 4–9 months at the time. Iontophoresis, also called electromotive drug administration, with tap water or an anticholinergic can be used. However, it requires that the patient dedicates a significant amount of time to therapy daily. Surgical intervention by thoracic sympathectomy is reserved for patients who failed or cannot tolerate non-invasive therapies.

SURGICAL PROCEDURE

Before the introduction of endoscopy, thoracic sympathectomy was performed through several different approaches: posterior, supraclavicular, anterior transthoracic, and transaxillary. The posterior approach, described by Adson for bilateral sympathectomy, requires significant muscle dissection and osteotomies, resulted in debilitating pain and disfiguring scars.⁷ The supraclavicular approach has a difficult exposure of ganglia below T3 and higher incidence of Horner's syndrome (up to 10%).⁸ The anterior transthoracic approach is done through a large incision from the parasternal to the anterior midaxillary line, and requires division of the pectoralis muscle. Finally, the transaxillary approach, the least destructive, has an oblique incision at the base of the axillary hairline from the latissimus dorsi to the pectoralis major.⁹ This approach is still used for patients who cannot or have failed thoracoscopic procedures. The disadvantage is that only one side can be done at the time and it requires a chest tube postoperatively.

Endoscopy revolutionized the procedure by minimizing tissue trauma, improving visualization, and illumination for a more accurate anatomical localization. In addition, both sides can be done in one setting as an outpatient procedure.

Anesthesia

A key point in thoracic surgery is to maintain a deflated ipsilateral lung. This can be achieved through placement of a

Fig. 10.1: Patient positioning in the lateral decubitus position.

double-lumen endotracheal tube and single lung ventilation. Alternatively, thoracoscopic sympathectomy can be performed with a single lumen endotracheal intubation and CO₂ insufflation to compress the lung. Contraindications may include prior thoracotomy, severe cardiopulmonary disease precluding single lung ventilation, and severe scoliosis.

Instrumentation

The procedure can be done with a 5-mm rigid endoscope, with a lens angle of 0–45° based on surgeon's preference. Other useful instruments include hook electrocautery or harmonic scalpel, long calibrated dissection tools, fan or sponge retractors, and suction irrigation.

Patient Positioning

For bilateral procedures, the patient is positioned supine with his arms at a 90° angle. Next, a 40° reverse Trendelenburg allows the deflated lung to fall away from the surgical site by gravitational pull. Care must be taken to not have the patient slide off the bed. This can be accomplished adjusting the bed to have the patient in a recliner position and using a footboard if necessary (Fig. 10.1).

For unilateral procedures, the patient is positioned in the lateral decubitus position, and is secured with straps and tape.

Approach and Sympathectomy

A 5-mm trochar is introduced in the midaxillary line of the fourth intercostal space. Carbon dioxide is insufflated

as needed, to a pressure of 10 mm Hg. The second port is introduced at the inferior axillary hairline, at the third intercostal space. The first port is used for the endoscope, and the second is the working port.

The sympathetic chain is identified running over the anterior surface of the posterior rib heads (Fig. 10.2). The first rib is not always well visualized but can be palpated. It is associated with a fat pad under that lays the stellate ganglion. Subsequent ganglia are adjacent, slightly caudal to respective rib heads. The second to fourth sympathetic ganglia are identified, the pleural space between ganglia is cauterized over the rib, the sympathetic chain is identified, cauterized and cut above and below the target ganglion. Sectioning of the T2-T3 ganglia is usually performed

for palmar hyperhidrosis, T2-T4 for palmar, and axillary hyperhidrosis. Alternatively, clips can be applied to the sympathetic chain without sectioning (Figs. 10.3A and B). The reversibility of the procedure through removal of clips has recently been debated.¹⁰

The nerve of Kunz represents an intrathoracic ramus that joined the second intercostal nerve to the ventral ramus of the first thoracic nerve, proximal to the point where the latter gave a large branch to the brachial plexus. It is an anatomical variant present in 40–80% of the general population.^{11,12} If present, it needs to be disconnected or excised.

Upon completion of the sympathectomy, a red rubber catheter is inserted in one of the ports, while the other is closed. The catheter is submerged in saline while anesthesia re-expands the lung. Bubbles confirm lung expansion. The red rubber is removed and the second incision is closed. A postoperative chest X-ray is essential to confirm lung expansion and minimal pneumothorax.

OUTCOMES AND COMPLICATIONS

Careful patient selection is the first parameter of a successful surgery. Published series have shown a significant decrease in perspiration for 93.4–100% of patients.² Freeman et al. reported a 6.6–12.5% recurrence of symptoms.² However, their success rate with reoperation was comparable to the initial surgery without significant morbidity.

Variable results have been observed for different ablation levels and techniques. T3 ablations were shown to result in lower incidence or severity of compensatory hyperhidrosis compared to T2 or T2-T4; T4 ablations in

Fig. 10.2: Endoscopic exposure of sympathetic chain.

Figs. 10.3A and B: Endoscopic clip placement on sympathetic chain.

lower incidence of severe anhidrosis.² A systematic review in 2008 revealed no difference in outcome with varying sympathectomy techniques: resection, ablation, and transection.² It also showed that inclusion of T2 in the sympathectomy improved patient outcome and had low rates of compensatory hyperhidrosis.

The most common neurological complication is compensatory hyperhidrosis, reported in 17–75% of patients. However, it usually improves within 6 months and is only severe in 5–10% of cases.² There are currently no conclusive evidence that a specific sympathectomy level reduces the incidence of hyperhidrosis.

Horner's syndrome can result from injury to the stellate ganglion. The incidence is reported as high as 24% in the immediate postoperative period, with long-term symptoms in 0–8% of patients.²

The most common pulmonary complication of thoracoscopic sympathectomy is pneumothorax. It has been reported in 7–17% of cases.² This delays patient discharge and, if symptomatic, may require chest tube placement. Pleural effusions have been reported, particularly in cases where the sympathetic chain was excised as opposed to disconnected. Subcutaneous emphysema in the thorax and neck can occur in up to 2% of cases.²

CONCLUSION

Thoracoscopic surgery is a safe minimally invasive outpatient procedure that can effectively treat primary hyperhidrosis. Patients can have a significant reduction in perspiration and maintain good socioeconomic circumstances.

Stereotactic Radiosurgery of the Spine

David M Neils, James McGee, Daniel R Fassett

Snapshot

- » Radiobiology
- » Technical Elements of SRS Delivery
- » Toxicity

INTRODUCTION

The role of radiotherapy (RT) in spinal oncology is well established with numerous studies showing the efficacy of RT in relieving pain and preserving functional neurological status from spine metastases.¹⁻³ Traditional RT is delivered via external beam radiation with moderate doses of radiation given over 10–20 fractions, typically on a 5-day per week schedule. Such a schedule may be inconvenient for patients and can delay systemic therapy. Further, standard fractionation, with low dosages of radiation, may not have a sufficient biological effect to control the tumors being treated. Higher doses of conventional RT may not only be more effective in treating the tumor but also put the adjacent neural structures at greater risk. Advances in planning software, target immobilization, imaging at the

time of treatment to ensure accuracy, and speed of radiation delivery allow many patients to safely receive higher doses of radiation per treatment for a greater biological effect while protecting radiosensitive adjacent tissues.⁴

Stereotactic radiosurgery (SRS) of the spine is a single high dose of radiation carefully shaped to the tumor target and given with imaging of the patient's internal anatomy (or implanted surrogate fiducial markers) to assure accurate dose targeting. Stereotactic body radiotherapy (SBRT) is a hypofractionated RT course typically consisting of two to five fractions whose dose is higher than traditionally delivered per fraction.⁴ The differences in the delivery of these forms of RT are summarized in Table 11.1. The basic premise of both SRS and SBRT is the delivery of radiation in such a manner to achieve a better clinical control of the tumor with fewer side effects and increased efficiency.

Table 11.1: Types of radiotherapy.

Therapy	Number of doses	Doses per fraction	Comments
Conventional radiotherapy	10	300 cGy	Split course
	5 + 5	500 cGy + 300 cGy	
Hypofractionated stereotactic body radiotherapy	4	4 Gy	All considered equivalent
	5	6 Gy	
	3	8 Gy	
	3	9 Gy	
Stereotactic radiosurgery	1	16–24 Gy	

By using image guidance and highly conformal doses, the radiation oncologist is able to target abnormal tissue but have a rapid dose falloff that will allow for tolerable doses of radiation to the surrounding normal tissues. Stereotactic radiosurgery and SBRT are similar in concept and delivery. The dose to the surrounding normal tissues, including the spinal cord, is often the deciding factor in the choice of conventional fractionation, single-fraction radiosurgery, or two to five fractions SBRT. The terms SRS and SBRT are often used interchangeably (i.e. five fraction radiosurgery) leading to some confusion in the literature. It is important to note that the radiation tolerance of normal tissues varies significantly as the number of fractions and time course of therapy change. So too, the chances of tumor control and the speed of symptom relief vary with the dose and time factors. Such variations need to be considered when outcomes in the literature are used to compare SRS, SBRT, conventional RT (with a greater number of fractions), and open surgical treatment.

The indications for treatment with SRS and SBRT are similar to the indications for conventional RT. The goals are typically palliation of pain, local disease control, and prevention of (or selectively reversing) neurological deficits.⁵ Current applications of these techniques are as single modality treatment for spinal metastases or as a salvage option for previously treated tumors, by either prior radiation⁶ or surgical resection. Increasingly, patients are treated with SRS or SBRT after surgical debulking of a portion of tumor. For tumors encroaching upon the spinal canal, surgical debulking can remove the tumor in close proximity to the spinal cord and allow for a safe radiosurgical dosage of radiation to the remaining tumor.

Stereotactic radiosurgery and SBRT have a number of advantages compared with conventional RT in the treatment of metastatic disease. The first significant advantage is that a higher dose of radiation delivered in a single setting will have a greater radiobiological impact upon the tumor, thereby broadening the spectrum of pathology amenable to treatment to include malignancies traditionally considered to be radioresistant such as melanoma, renal cell carcinoma, and sarcoma. Second, delivery of radiation with a rapid falloff of dose can reduce the complications related to RT such as esophagitis or radiation-induced myelopathy. Importantly for surgeons, the highly conformal nature of SRS allows for sparing of the skin and surrounding soft tissues, decreasing the risk of poor wound healing, and allowing earlier administration of radiation in the post-

operative patient. The smaller fields used in SRS and SBRT also lead to less bone marrow suppression with its adverse effects upon the utilization of chemotherapy. Finally, SRS and hypofractionated treatments are more convenient for patients in comparison to weeks of daily treatments with conventional RT.

RADIOBIOLOGY

Radiobiology is the study of the manner in which radiation interacts with living cells. As a result of a longer history of the application of SRS to cranial pathologies, most of the clinical advantages of SRS in other locations in the body are inferred from years of cranial radiosurgery experience. Radiation doses, as delivered in conventional fractionation, lead to free-radical formation largely mediated by oxygen in the tissues. Conventional RT typically induces death in target cells by means of double-strand deoxyribonucleic acid (DNA) breaks.⁷ These double-strand breaks can ultimately lead to cell death. Conventional RT is effective when tumor cells are more sensitive to the treatment than the surrounding normal tissues. The relative radioresistance of some pathologies may reflect their ability to repair the damage that ionizing radiation does to their DNA. Pathologies that are resistant to radiation typically are tumors that are able to repair the damage done to their DNA by the relatively small daily exposures delivered by the conventional RT. Conventional RT is also dependent upon the varying sensitivity of cells to radiation damage based upon their place in the cell reproductive cycle with radiosensitivity decreasing during the times when the DNA is not undergoing active synthesis or mitosis.

Stereotactic radiosurgery delivers a much higher dose effect in a shorter time frame, changing the radiobiology compared with that of conventional RT. While DNA effects are still important, additional mechanisms of cell death are undoubtedly involved. Higher doses per fraction impact the vascular endothelium. Inferring from the cranial experience with SRS on arteriovenous malformations, doses >10 Gy in a single fraction have a marked influence on vascular endothelium that is not seen with conventional radiation dosing.⁸ The end result of exposure to high-dose ionizing radiation is endothelial hypertrophy and obliteration of the microvascular tumor environment. This data is supported by animal models analyzing the effects of radiation.⁹ Other equally important mechanisms of enhanced tumor cell killing with radiosurgery are being studied.¹⁰

Figs. 11.1A and B: Patient immobilized for stereotactic radiosurgery treatment on Trilogy system.

TECHNICAL ELEMENTS OF SRS DELIVERY

Advances in target planning, immobilization, radiation delivery, and target motion tracking have led to the precision necessary for the delivery of SRS.⁴ There are a number of commercially available systems for the delivery of SRS/SBRT. These systems include Novalis, TomoTherapy HI-ART Helical Tomotherapy, CyberKnifeElekta Synergy S, and Varian Medical Systems Trilogy and TrueBeam linear accelerators with RapidArc. The patient's body and subsequently the target are immobilized by different techniques based upon the commercial system. Common ways of immobilization are masks for cervical pathology and conformational body support for thoracic and lumbar pathologies.⁴ An example of a patient immobilized for radiosurgery is shown in Figures 11.1A and B.

Planning for SBRT/SRS is typically undertaken by a multidisciplinary team including spine surgeons, radiation oncologists, and medical physicists. The preprocedural workup should include either computed tomography (CT) scan or magnetic resonance imaging (MRI) to accurately identify the target pathology as well as the important surrounding anatomy including the spinal cord and esophagus. Computed tomography myelography for radiation treatment simulation is indicated to accurately locate the spinal cord or spinal nerve roots in planning for tumors that are in close proximity to the spinal cord. In some instances, 3D image fusion of CT and MRI data in the radiation treatment planning systems may be adequate for the identification of the important anatomy. Image fusion can result in some imprecision that must be considered if tumor is

in proximity to critical neurological structures such as the spinal cord. Imaging studies must be obtained to allow for optimal delineation of the tumor extent as well as organs at risk for radiation injury from treatment. In conventional RT, surrounding normal tissues are covered by the radiation treatment. Although this can lead to damage to surrounding normal tissues, it could potentially be beneficial in situations when the tumor is invading the surrounding tissues. Radiosurgery demands detailed contouring to include all areas of tumor extension as well as exact location of critical normal structures that can be damaged by high dose per fraction radiation. The exact specifics on planning will vary with the commercially available system used to administer SRS.

Target Planning

In order to effectively administer SRS, the treating physician(s) must develop a treatment plan. This must be done manually by the treating team by defining the tumor as well as any adjacent organs at risk for radiation damage on pertinent imaging studies. Three important volumes are commonly defined for tumor volumes: gross tumor volume (GTV), clinical target volume (CTV), and planning target volume (PTV). The International Spine Radiosurgery Consortium established guidelines for the definition of these three important volumes as summarized in Table 11.2. Gross tumor volume is the contoured volume of the tumor based upon available imaging studies. Clinical target volume is the volume surrounding the GTV suspicious for microscopic disease spread. The PTV is an intentional circumferential expansion around the CTV to account

Table 11.2: Important clinical volumes in stereotactic radiosurgery.

Target volume	Included
Gross tumor volume (GTV)	Contour gross tumor based upon all imaging including epidural and paraspinal components
Clinical target volume (CTV)	GTV plus abnormal bone marrow signal and a expansion of bony GTV to account for microscopic and subclinical tumor spread
Planned target volume (PTV)	Uniform expansion of CTV of 3 mm or less, this should be contoured to avoid spinal cord and should contain both the GTV and CTV

Source: Adapted from Cox BW, Spratt DE, Lovelock M, et al. International Spine Radiosurgery Consortium consensus guidelines for target volume definition in spinal stereotactic radiosurgery. *Int J Radiat Oncol Biol Phys.* 2012;83(5):e597-605.

for setup inaccuracy specific to the system and patient being treated, often a margin of 1–3 mm. The PTV is the volume to which radiation delivery is planned.¹¹ The circumferential expansion of the PTV must be well considered and cannot include the spinal canal or adjacent esophagus in the PTV.

Radiosensitive structures typically considered at risk given their proximity to spine include the spinal cord, cauda equina, nerve roots, esophagus, trachea, oropharynx, and kidneys. As the dose per fraction increases, other organs have to be considered for both acute and long-term effects, including the bowel. All of these organs have varying radiation tolerances as the dose per fraction and the number of fractions change. Organ tolerance and complications are discussed in detail in the toxicity section. An example of a planning simulation is shown in Figures 11.2A and B.

Spine SRS for Metastatic Pathology

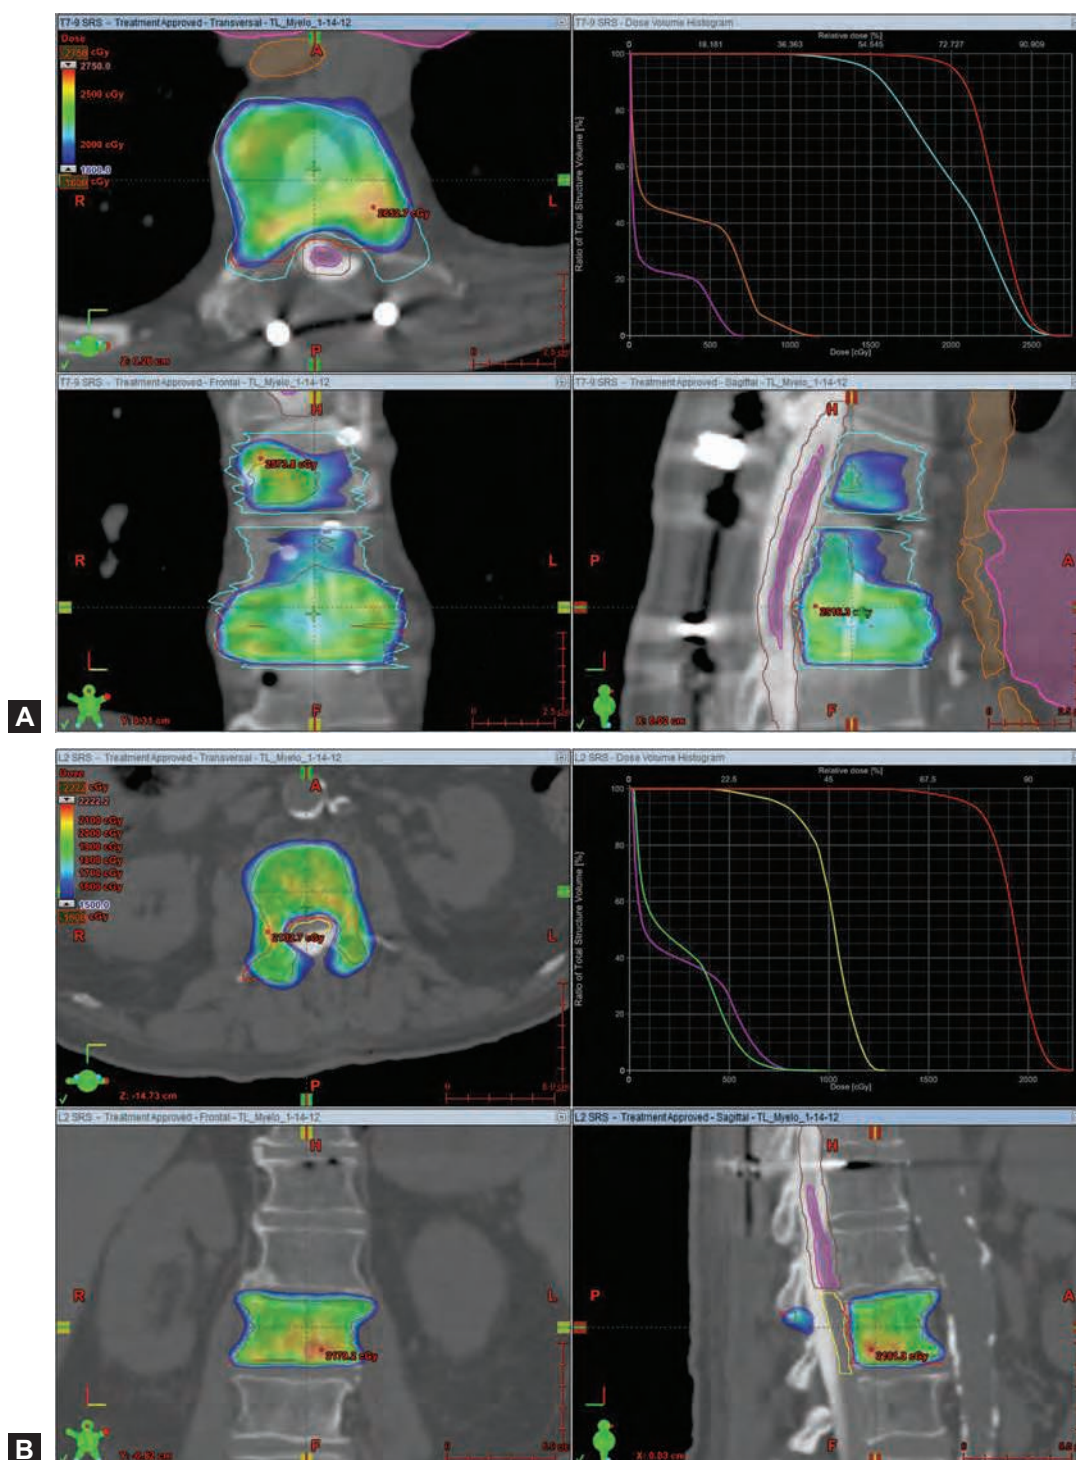

The decision to apply SRS to a particular lesion is similar to other oncologic decisions in that tissue histology of the lesion is the cornerstone of decision making. This is the result of the variable sensitivity of various primary histologies to radiation treatments as is summarized in Table 11.3.⁵ As shown in the table, histologies range from relatively radiosensitive (favorable pathologies) to relatively radioresistant (unfavorable pathologies). In general, lymphoma, seminoma, small cell lung carcinoma, myeloma, and other nonsolid organ tumors are classified as very

radiosensitive tumors and are often excluded from surgical and radiosurgical studies. At the other end of the spectrum are the relatively radioresistant tumors, which typically include sarcoma, melanoma, gastrointestinal tumors, nonsmall cell lung carcinoma, and renal cell carcinoma. Intermediate range tumors typically include breast and prostate carcinoma. As a rule of thumb, conventional RT is the frontline treatment of radiosensitive metastatic tumors. In the setting of intermediate and resistant tumors, multidisciplinary decision making is recommended with consideration for a combination of conventional surgery, SRS, and conventional RT depending upon the condition of the patient and the experience of the treating team.

The effect of SRS on particular pathologies has not been systematically studied to this point, and the best available data is from large prospective cohort studies.¹² This data is difficult to interpret related to the heterogeneity of the metastatic spinal tumor patient population. Patients often present to SRS centers having undergone highly variable pretreatment management. Additionally, patient characteristics such as performance status and chemotherapy treatments can be confounding variables in assessing data from trials involving patients with advanced metastatic disease. Given these difficulties, the best available analysis of these cohort studies comes from literature reviews. For local tumor control SRS ranged from 75% to 100% effective, while for pain control/improvement SRS was 36–97.3% effective. In this same literature, SRS produced side effects in the form of radiation-induced myelopathy in 0–4% of cases. The data on the treatment of malignant pathologies with spinal SRS is summarized in Table 11.4. Both the rate of local recurrence and radiation-induced myelopathy are dependent upon the delivered dose of radiation, a single dose of at minimum 15.1 Gy to the GTV was associated with 100% local control in a study of 79 patients with 91 consecutive tumors.¹³

Spinal SRS for Primary CNS Pathologies

Spinal SRS is predominantly applied to malignant pathologies as metastases account for the greatest percentage of tumors in the spinal column. However, based upon the experience gained with cranial radiosurgery, primary lesions of the spinal column are being studied for SRS treatment. The initial experience with cranial stereotactic radiosurgery has demonstrated the effectiveness and safety of SRS for trigeminal neuralgia,²⁹ arteriovenous malformations,³⁰ and multiple types of benign intracranial tumors.^{31,32}

Figs. 11.2A and B: Treatment plan from a 67-year-old man with a history of metastatic melanoma. The patient had multiple lesions including a pathological burst fracture of T9 and lesions in T3, T8, and L2. The treatment plan utilized a computed tomography myelogram to better localize the spine cord. A magnetic resonance imaging (MRI) was also fused with this myelogram to help localize the tumors, but the MRI images are not shown here. (A) Plan for the T9 and T8 tumors is shown. Note the presence of methylmethacrylate (bone cement) and Steinman pin in the area of the T9 vertebral body and the pedicle screws with rods posteriorly. The spinal cord is depicted in purple, the esophagus is shown in orange, and the tumor is blue-green. (B) Plan for L2 metastasis is shown with the spinal cord (purple), cauda equine (yellow), and tumor (blue) outlined.

Table 11.3: Radiosensitivity based upon histology.

<i>Histology</i>	<i>Sensitivity</i>
Lymphoma	Radiosensitive
Seminoma	Radiosensitive
Myeloma	Radiosensitive
Small cell lung	Radiosensitive
Breast	Intermediate
Prostate	Intermediate
Sarcoma	Radioresistant
Melanoma	Radioresistant
Gastrointestinal	Radioresistant
Nonsmall cell lung	Radioresistant
Renal	Radioresistant

Source: Adapted from Gerszten PC, Mendel E, Yamada Y. Radiotherapy and radiosurgery for metastatic spine disease: what are the options, indications, and outcomes? *Spine* (Phila Pa 1976). 2009;34(22 Suppl):S78-92.

Two separate large studies have been published utilizing spinal SRS for benign intradural extramedullary pathology.^{33,34} The results based upon pathology are summarized in Table 11.5. Overall these studies have shown the safety of SRS for these pathologies with 4%³³ and 1%³⁴ of treated intradural tumors developing symptoms referable to radiation-induced myelopathy. These studies also demonstrate the durability of SRS for meningiomas, schwannomas, and neurofibromas with only a single case of radiographic progression in the 176 pooled tumors over follow-up ranging from 8 to 87 months. Stereotactic radiosurgery has also been used to treat sarcomas,³⁵ hemangioblastomas,³⁶ and chordomas.³⁷

Spinal SRS as Adjuvant Treatment to Surgery

Metastatic disease is the most common indication for the use of SRS, but the application of this technique has not

Sachdev et al., 2011 ³⁴	Overall	103	19.4 Gy (14–30)	Actuarial control rate of 95% at 4 years		6–87 months	1 case of transient myelopathy at 9 months
	Meningioma	32			57% improved, 43% unchanged		
	Neurofibroma	24			17% improved, 50% minimal change, 33% worsened		
	Schwannoma	47			53% improved, 36% minimal change, 14% worsened		

yet been fully realized with many patients still being seen for “salvage” therapy after failing conventional RT. Most studies also indicate that for radioresistant and intermediate sensitivity tumors, the response time and duration of symptom relief is much better for radiosurgery than conventional RT. Stereotactic radiosurgery is also being increasingly utilized as an adjunct to surgical decompression and/or stabilization.

Following surgical treatment of metastatic spinal disease, the technical delivery mechanisms of SRS/SBRT have the advantage of less radiation to the skin and theoretically fewer wound breakdown problems. This allows for earlier treatment of patients after open surgical procedures with high local control rates. Itshayek et al.³⁸ recently reviewed the timing of RT following surgical treatment of metastatic disease. This review found no study definitively addressing this issue but recommend based upon the physiology of wound healing that RT be delayed at least 1 week following surgery. Another concern in the postoperative patient is the concern for instrumentation failure, a single retrospective study³⁹ compared instrumentation

failure in SRS and RT and found a nonsignificant 0% versus 43% instrumentation failure rate for SRS and RT adjuvant treatments respectively. Moulding et al.⁴⁰ reviewed their experience with high dose 24 Gy single fraction treatments following surgical excision and found a 1-year local failure rate of 6.3% compared with 20% in patients treated to 18–21 Gy. There were no cases of wound healing problems in this study.

TOXICITY

The maximum dose that can be delivered to a tumor with radiosurgery is typically limited by the maximum safe dose to surrounding structures. In most cases of spinal stereotactic radiosurgery, the most sensitive structure is the spinal cord. There are a number of different methods for planning a treatment to minimize adverse effects on the spinal cord including a maximum point dose to the spinal canal or thecal sac. The spinal cord is, like other CNS tissues, increasingly more at risk for radiation damage as the dose per fraction that it receives increases. In radiobiology, this is expressed as a low alpha/beta ratio. The alpha/beta ratio

Table 11.6: Adjacent tissue tolerance.

<i>Tissue</i>	<i>Volume (mL)</i>	<i>Volume max (Gy)</i>	<i>Max point dose (Gy)</i>
<i>Single fraction</i>			
Spinal cord	<0.025	10	14
Cauda equina	<5	14	16
Esophagus	<5	14.5	19
Great vessels	<10	31	37
Trachea	<4	8.8	22
Skin	<10	14.4	16
Lung	1500	7	
Renal	200	8.4	
<i>Three Fraction</i>			
Spinal cord	<0.25	18	22
Cauda equina	<5	21.9	24
Esophagus	<5	21	27

for CNS tissues is among the lowest in the body. Stereotactic radiosurgery and SBRT are only safe if the dose to the spinal cord is accurately known and restricted both in the treatment planning and in dose delivery. The spinal cord is a serial organ, not a parallel organ, and consequently any portion of the cord at any level being damaged is a major complication. Ryu et al.⁴¹ examined the effect of SRS on the spinal cord volume defined as a volume 6 mm above and below the tumor volume and had a single case of radiation-induced myelopathy in 86 patients who survived a year. They concluded from this experience that a dose of 10 Gy to 10% of the spinal cord above and below the tumor volume is safe. Another means of defining spinal cord tolerance is as a point tolerance. Sahgal et al.⁴² examined 5 cases of radiation-induced myelopathy with 19 matched patients and concluded that using maximum point dose measurements 10 Gy in a single fraction is safe and up to 5 fractions with a biologically effective dose of 30–35 Gy with an α/β of 2/2 to the thecal sac is safe. We recommend the use of maximum dose points, not volumes of cord, given the consequences of cord injury. Timmerman⁴³ published the dose constraints used in SBRT, the

data of which has been adapted to spine SRS adjacent organs in Table 11.6.

CONCLUSION

Stereotactic radiosurgery or SBRT are viable options in the treatment of metastatic disease to the spine. The treatment has been shown to be both safe and effective at both pain control and local tumor control. The exact role of SRS as the initial treatment of metastatic disease, as salvage therapy for failed conventional RT, and as an adjuvant to conventional surgical treatment is not fully defined; however, the treatment has been shown to be safe and effective in all of these settings. Stereotactic radiosurgery holds promise in the treatment of relatively radioresistant tumors by delivering a higher dosage of radiation and providing additional pathways for tumor cell death compared with conventional RT. Future studies will continue to delineate the optimal dosing strategies in different pathologies and clinical situations.

KEY POINTS

- Advances in imaging, targeting, and radiation delivery have allowed for the precise delivery of highly conformal radiation to the spine.
- Stereotactic radiosurgery and SBRT are typically reserved for patients who have failed conventional RT, or who have radioresistant tumors.
- Stereotactic radiosurgery/stereotactic body RT have been shown to be 75–100% effective at local metastatic tumor control and 36–97% effective for pain control in metastatic disease.
- There is an increasing role for SRS/SBRT in the treatment of primary spinal tumors including meningioma, schwannoma, ependymoma, chordoma, sarcoma, and hemangioblastoma.
- Stereotactic radiosurgery/stereotactic body RT has been shown to have a low toxicity/complication rate as long as targets are carefully planned to limit the dose to the spinal cord.

INTRODUCTION

One of the most feared complications in spinal surgery is neurological injury. Although an infrequent occurrence, iatrogenic neurological injury can be a devastating complication leading to serious sequelae and possible permanent impairment. In recent decades, there has been much technological advancement in spine surgery leading to a broader role for treatment of complex spinal pathologies with surgery and improved outcomes. Intraoperative neurophysiological monitoring (IONM) has played an integral role in this advancement. In recent decades, IONM has expanded in scope, finding application in a wide range of surgical procedures where there is elevated risk of neural compromise. Primarily, IONM serves to prevent or minimize neurological sequelae by providing a pathway of early intraoperative detection of evolving neurological injury. Intraoperative neurophysiological monitoring is based on the premise that neurophysiological activity changes in a measurable and reversible way before the onset of

permanent neurological deficit, thus opening a window of opportunity for correction.¹

As it applies to spine surgery, IONM first emerged from the laboratory setting and was initially utilized to detect impending iatrogenic injury of the spinal cord during pediatric deformity correction.²⁻⁶ As innovations in spinal instrumentation paved the way for surgical advancements, neuromonitoring technologies evolved in parallel and allowed surgeons to become more aggressive with their therapeutic goals and techniques.^{7,8} While these advancements in surgical techniques enjoyed a high success rate for deformity correction, they were not without their share of neurological complications. Indeed, these complications were highlighted in a report by the Scoliosis Research Society, which chronicled the potential for acute neurological deficit associated with these new techniques.⁹

Initially, intraoperative monitoring of spinal cord function was limited to survey of the somatosensory tracts. The first intraoperative evaluations of motor function consisted of a wake-up test, wherein anesthesia was reversed

to the point at which the patient could volitionally move his extremities.¹⁰ There were many logistical difficulties associated with the Stagnara wake-up test such as reversing anesthesia, having the patient follow commands on the operating table, reintroducing anesthesia and not the least of which was not allowing for continuous monitoring of motor function. The inability to continuously monitor motor function was a void in IONM, limiting its usefulness throughout surgery. This void was filled with the discovery that transcranial electrical stimulation of the motor cortex produced recordable potentials in contralateral muscles.¹¹ Boyd and colleagues¹² adapted the technique for monitoring corticospinal tract function during surgery. Subsequent advances in monitoring equipment, anesthesia protocols,¹³ and methodology¹⁴ have allowed for routine continuous monitoring of spinal cord motor tract function during spine surgery.

Risk of neurological injury may extend beyond the spinal cord to include nerve roots. Spontaneous electromyography (EMG) was introduced to spine surgery in the early 1990s as a means of detecting nerve root irritation in real time.^{15,16} Other advances included adaptation of EMG techniques to test for medial pedicle wall breaches following pedicle screw placement.^{17,18} Given the complex nature of spine surgery, individual monitoring modalities cannot adequately survey all at-risk neural elements. Thus, a multimodality IONM approach is required for comprehensive neurophysiological surveillance and has gained increased acceptance in recent years.¹⁹⁻²²

DEVELOPING THE IONM PLAN

The neuromonitoring plan must be developed as an individualized patient-specific plan that encompasses the entirety of the patient's medical history, present pathology, and the plan of treatment. Because IONM data are influenced by a wide range of factors, the patient's medical history should be thoroughly reviewed by the neurophysiologist prior to surgery. A bedside examination should include objective assessments of strength, light touch, proprioception, reflexes, and cranial nerve motor functions. All preexisting neurological deficits should be documented. A chart review should also be conducted in order to identify factors in the patient history that could adversely influence the quality of neuromonitoring data. Some influencing patient factors of particular importance are neuromuscular and neurodegenerative diseases, diabetes mellitus, hypotension/hypertension, stroke, radiation therapy, abnormal blood panels (e.g. low hemoglobin or high creatinine), and

prior surgery involving the brain, spine, or joints. Finally, the neurophysiologist should review radiographic imaging to integrate pathology with presentation. Each IONM test modality measures the functional integrity of a different part of the nervous system, with little overlap. As such, test modalities are selected after at-risk elements of the nervous system have been identified.^{1,23}

TRANSCRANIAL ELECTRIC MOTOR EVOKED POTENTIALS

Transcranial electric motor evoked potentials (tceMEPs) are used to monitor the integrity of efferent spinal cord pathways mediating motor function, particularly the corticospinal tract. Typically, intramuscular needle electrodes are used to record myogenic responses to anodal electrical stimulation of contralateral primary motor cortex.^{11,12} Myogenic tceMEPs are highly sensitive to acute changes in spinal cord motor function.²⁴⁻²⁶ While there is no universal consensus on warning criteria for significant change,^{27,28} tceMEP amplitude attenuation >65% from baseline that cannot be explained by technical or anesthetic factors warrants prompt surgical attention.²⁶ Figure 12.1 illustrates how appropriate identification and timely reversal of the proximate cause of tceMEP change can result in the recovery of motor conduction and avoidance of postoperative neurological deficit. Myogenic tceMEPs are also sensitive to the effects of anesthesia, particularly inhalational agents, because they require depolarization at multiple synapses throughout the nervous system, including local interneurons of the cerebral cortex, and α -motoneurons of the spinal cord.^{29,30} An alternative, but more invasive, technique for monitoring spinal cord motor function is recording the neurogenic D-wave. In response to motor cortex stimulation, descending volleys are recorded with an epidural or subdural electrode situated over the dorsomedial surface of the spinal cord. D-waves are stable, reliable, and highly resistant to anesthetic effects because they are mediated asynchronously.^{12,31}

SOMATOSENSORY EVOKED POTENTIALS

Somatosensory evoked potentials (SSEPs) are used to monitor the functional integrity of spinal cord sensory tracts specific to the dorsal column-medial lemniscus system. Electrical stimulation of ulnar or median nerves activates the cuneatus tract, while peroneal or posterior

Fig. 12.1: Reversible transcranial electric motor evoked potential (tceMEP) attenuation during posterior T2-L4 instrumented fusion with pedicle screw fixation for idiopathic scoliosis, demonstrating effect of intervention following neuromonitoring alert. Transcranial electric motor evoked potentials were of sufficient size and consistency for reliable monitoring at baseline and just prior to correction of the deformity. During the course of correction, tceMEPs from all left side myotomes below the level of correction exhibited marked amplitude attenuation with no concomitant change in SSEPs, right side tceMEPs, mean arterial blood pressure, or depth of anesthetic hypnosis. Following a surgical pause and increase in the MAP from 73 to 93 mm Hg, tceMEPs gradually improved and were consistent with baseline by closure. This procedure was staged, and the deformity was corrected at a later date without compromise of neurological function. (FD: First dorsal interosseous; RA: Rectus abdominis; IP: Iliopsoas; QD: Quadriceps; TA: Tibialis anterior; AH: Abductor hallucis; AS: External anal sphincter; Prefix L indicates the left side).

tibial nerve stimulation activates the gracilis tract, resulting in subcortical responses recorded with surface or subdermal needle electrodes placed near the second cervical vertebra and cortical responses recorded with electrodes placed in the scalp over somatosensory cortex.³² Cortical SSEPs are particularly susceptible to inhalational anesthetic agents, while subcortical SSEPs are more resistant.²⁹ Somatosensory evoked potential amplitude attenuation >50% from baseline that cannot be explained by technical or anesthetic factors warrants prompt surgical attention.^{33,34} Because SSEPs reflect dorsal column function, they may remain unchanged in the face of evolving motor deficit.^{26,35} The dorsal columns can be mapped in order to identify the median raphe of the spinal cord when a dorsal myelotomy is planned. Intramedullary tumors can distort the anatomy of the dorsal spinal cord, making it difficult to identify the posterior median sulcus visually. Dorsal column mapping (DCM) will identify the electrophysiologic midline, allowing the surgeon to perform a myelotomy that can largely spare dorsal column function. There are a number of ways to perform DCM. If a 6–8 lead electrode strip is placed across the spinal cord in the transverse plane, one can stimulate the spinal cord selectively and record SSEPs from the scalp, using phase reversal to identify the midline.³⁶ This same electrode could be used to record dorsal column volleys in response to peripheral nerve stimulation.³⁷ Finally, one can stimulate the dorsal spinal

cord and record antidromic responses from the peripheral nerves.³⁸ While each of these techniques can be technically challenging, their potential for reduction of postoperative morbidity of dorsal column function is promising.

ELECTROMYOGRAPHY

Intraoperative EMG is used to monitor somatic efferent nerve activity and can be used to accurately assess the functional integrity of individual nerves when they are subjected to direct electrical stimulation.^{39,40} The basic premise of EMG is that depolarization of a motor nerve produces a recordable electrical potential within one or more muscles innervated by that particular nerve. Electromyographic activity is recorded using intramuscular needle electrodes. Accurate interpretation of EMG is facilitated by simultaneous visual and auditory monitoring, so a speaker is used in parallel with a visual display to provide concurrent auditory feedback to the neurophysiologist and surgeon.

Spontaneous EMG is recorded throughout the course of surgery providing real-time feedback whenever a motor nerve is activated. Neurotonic EMG, characterized by irregular, high frequency (50–300 Hz) burst and train activity, is of greatest concern as it may be caused by nerve compression, traction, or blunt trauma.^{40,41} By contrast,

Fig. 12.2: Brainstem auditory evoked potential (BAEP) attenuation during posterior C1-3 instrumented fusion with lateral mass screw fixation for stabilization of an odontoid fracture, demonstrating sensitivity to brainstem infarct. Brainstem auditory evoked potentials were characterized by clearly formed waves I, III, and V, and bilaterally symmetrical I-V interpeak intervals just prior to placement of lateral mass screws (20:13). Following placement of screws (20:23), BAEPs exhibited marked bilateral amplitude attenuation, with no change in global EEG, transcranial electric motor evoked potentials, or somatosensory evoked potentials. Following a surgical pause, BAEPs began to show some signs of improvement. Subsequent postoperative studies revealed a posterior inferior cerebellar artery infarct. (Traces in the two columns on the left show BAEPs to stimulation of the left ear. Traces in the two columns on the right show BAEPs to stimulation of the right ear. Cpz, A1 and A2 designate recording electrode positions according to the International 10-20 System).

relatively regular, low frequency activity is usually benign and in some circumstances may indicate insufficient patient hypnosis.⁴¹

Electromyographic trains lasting longer than 10 seconds have been associated with postoperative deficit;⁴² however, absence of spontaneous EMG activity is not necessarily indicative of stable nerve function. Indeed, neurotonic EMG may be absent following serious nerve injury, including sharp dissection.^{43,44} Thus, spontaneous EMG has limited sensitivity to nerve injury.

Stimulus-triggered EMG is used in spine surgery to identify nerves, establish the functional integrity of nerves, rule out the presence of nerves within muscle or tumor mass, and to test for medial breach of pedicles following screw placement. A handheld probe is used to deliver electrical stimulation to the site of interest. When a nerve is depolarized, a response is recorded in the form of a compound muscle action potential (CMAP). The recording window is time locked to the onset of the stimulus, allowing the latency and amplitude of CMAPs to be quantified and compared. The *threshold*, operationally defined as the minimum current necessary to trigger a CMAP, can be used to gauge the functional status of the nerve that

is stimulated³⁹ and is also useful in differentiating neural versus non-neural tissue.⁴⁵

**BRAINSTEM AUDITORY
EVOKED POTENTIALS**

Brainstem auditory evoked potentials (BAEPs) are used to monitor vascular perfusion of the brainstem⁴⁶ and can be useful in high cervical spine surgery where there is increased risk for brainstem infarct secondary to vertebral artery injury.^{23,47} Auditory click stimuli are delivered to the ears through expandable foam ear buds inserted into the external auditory canal, and responses are recorded from electrodes placed near the ear/mastoid and vertex.⁴⁸ The BAEP consists of a waveform with five short-latency peaks that reflect neuronal activity in the ascending auditory pathway. The neural generators for the peaks are (I) distal auditory nerve, (II) proximal auditory nerve, (III) cochlear nucleus, (IV) superior olivary complex, and (V) lateral lemniscus or inferior colliculus.⁴⁹⁻⁵¹ A major ischemic accident secondary to vertebral artery compromise may result in disappearance of waves I-V.⁴⁶ When these changes do not resolve during the course of surgery, postoperative deficits may be expected.^{50,52} Figure 12.2 shows a BAEP

change during posterior C1-3 instrumented fusion with lateral mass screw fixation for a dens fracture.

■ OTHER NEUROMONITORING MODALITIES

In addition to the tests described above, there are a number of other monitoring modalities that can be of value during spine surgery. In particular, spinal cord function can be evaluated intraoperatively with tests that involve direct stimulation of and/or recording from spinal cord.³¹ These tests include spinal-cord-to-spinal-cord stimulation and recording,⁵³ spinal cord stimulation with peripheral nerve recording,⁵⁴ and spinal cord stimulation with muscle recording.⁵⁵

Spinal cord, spinal nerve root, and peripheral nerve functions can be evaluated with the use of intraoperative reflex tests. The H-reflex, for example, is a monosynaptic response that is recorded from muscle after electrical activation of an afferent nerve (e.g. gastrocnemius CMAP following posterior tibial nerve stimulation). The H-reflex has been used to monitor spinal cord, nerve root, plexus, and peripheral nerve function and has been used for research as a measure of the level of spinal cord excitability.⁵⁶ Similarly, the bulbocavernosus reflex (BCR) is a polysynaptic response recorded from the anal sphincter muscle following penile/clitoral electrical stimulation and has been used to monitor lower sacral nerve roots and the conus medullaris.⁵⁷ As with other tests, the relative merits of these modalities should be evaluated in the context of a multimodality approach to IONM.

■ IMPLEMENTING AND OPTIMIZING IONM

Proper execution of IONM requires extensive education and training on the part of the neuromonitoring team.¹ In addition to being technically skilled, the neurophysiologist in the operating room should be well versed in neuroanatomy, neurophysiology, neuropharmacology, and the relevant medical literature. Additionally, the neurophysiologist must possess strong communication skills and be familiar with the surgical procedure and anesthetic priorities. The success of IONM requires close, ongoing cooperation and communication between the IONM and anesthesia and surgical teams. It has been shown that hemodynamics, diabetes, and inhalational anesthetic technique are independent, but additive, factors that predic-

tably interfere with reliable recording of tceMEPs.⁵⁸ The effect of inhalational anesthetics on myogenic tceMEPs is particularly pronounced because these signals must overcome the effects of these agents on synaptic transmission in the spinal cord.³⁰ For these reasons, total intravenous anesthesia (TIVA) is oftentimes recommended to facilitate IONM, particularly when tceMEP monitoring is indicated.^{29,59,60}

The patient must also be sufficiently free of pharmacological blockade of the neuromuscular junction to allow both tceMEPs and EMG to be recorded with adequate sensitivity. A “train-of-four” test is sensitive to the number of bound nicotinic acetylcholine receptors and so provides an accurate, real-time assessment of the degree of neuromuscular blockade.⁶¹ Short acting neuromuscular blocking agents, administered to facilitate intubation and exposure, should be discontinued thereafter to facilitate sensitive tceMEP and EMG monitoring. The use of partial NMB has the potential for confounding interpretation of these signals because of difficulty maintaining a constant level of partial blockade, and because of the variable effects that partial blockade has on different muscle groups,⁶² particularly in patients with preexisting neurological dysfunction.⁶³

■ MECHANISMS OF INJURY AND REVIEW OF INTERVENTION STRATEGIES

The spinal cord and spinal nerve roots can be injured intraoperatively by a variety of primary mechanisms, including but not limited to compression, contusion, shear, distraction, laceration, ischemia, and thermal-related injury. As with all injury, a secondary biochemical process ensues. This secondary physiological reaction further exacerbates the primary injury and can include hemorrhage, vasospasm and loss of autoregulation, edema, axonal and neuronal necrosis, electrolyte imbalance, free radical production and lipid peroxidation, neurotransmitter accumulation, and apoptosis.⁶⁴⁻⁶⁶

While not all iatrogenic spinal cord injuries can be prevented or reversed, interventional strategies for evolving injuries endeavor to limit the extent and duration of injury. When IONM data are consistent with evolving spinal cord injury during surgery, the surgical team should be notified immediately. A surgical pause should be initiated, allowing the neurophysiologist to rule out all technical and anesthetic explanations for the IONM change, as well to avoid possible exacerbation of injury. Depending on

the proximate cause of neurophysiological change, the patient can be repositioned, spinal hardware and interbody graphs can be adjusted or explanted, distractive forces can be released, or irrigation can be applied to the neural elements in question. To address possible hypoperfusion of the spinal cord, mean arterial blood pressure should be elevated.²⁴ In some cases, intraoperative administration of steroids may be considered,⁶⁷ although this remains controversial.⁶⁸ As a prophylactic measure, close attention should be paid to maintenance of adequate blood pressure throughout the course of each spine procedure. This may require volume resuscitation using crystalloid, maintenance of a normal hematocrit, and administration of vasopressors.⁶⁵

IONM DURING CERVICAL SPINE SURGERY

Risk factors for neurophysiological deterioration during cervical spine surgery include preoperative myelopathy, long segmental extent of surgery, upper cervical surgery, use of instrumentation, and application of corrective forces to the neck.⁶⁹ Irrespective of whether cervical spine surgery employs an anterior or posterior approach, spinal cord function should always be monitored with both tceMEPs and SSEPs from both the upper and lower extremities. When the surgical manipulation poses risk to C5-C8 nerve roots, tceMEPs and free-running spontaneous EMG should be recorded from myotomes that are innervated by those roots.

Some pathologies of the cervical spine predispose the patient to elevated risk for neurological complications secondary to neck positioning. These include fracture/dislocation, cord compression, marked kyphosis, severe myelopathy, foraminal stenosis, ossification of the posterior longitudinal ligament, and space-occupying lesions. To the extent possible, a neutral neck position should be maintained during intubation and positioning. When the risk for injury is elevated, many anesthesia teams elect to perform an awake, fiberoptic intubation (AFI), which limits extension of the cervical spine while the airway is secured.^{70,71} The AFI also permits neurological assessment following intubation and sometimes final positioning.⁷² In the event that AFI is not available, or not possible, acquisition of postinduction, preintubation baseline tceMEPs is strongly recommended when the patient's pathology suggests elevated risk for extension injury. These responses form the basis for comparison with responses obtained following intubation. Appropriate neurophysiological monitoring

of the cervical spinal cord during this critical period requires significant preoperative planning, clear interpersonal communication, and a cooperative anesthesia team.

In addition to the risks associated with intubation, potential neurological complications secondary to patient positioning can be significant in cervical spine surgery. Destabilizing pathology of the cervical spine elevates the risk for new onset injury, particularly during prone positioning of the patient. Schwartz et al.⁷³ found that 1.8% of patients undergoing anterior cervical spine surgery had evidence of impending neurological injury. For many spinal procedures, surgical positioning can be critical. Positioning for surgery of the lower cervical spine and cervicothoracic junction can be particularly challenging with patients who have a large body habitus. Many times this can be addressed by applying countertraction to the shoulders in order to accommodate surgical exposure and lateral intraoperative radiography. However, a brachial plexus stretch or compression injury can sometimes occur from excessive countertraction. Also, circumferential tape around the arms can compress ulnar, median, or radial nerves. Somatosensory evoked potentials to stimulation of upper extremity peripheral nerves, as well as tceMEPs recorded from upper extremity myotomes, are particularly sensitive to impending peripheral nerve injury.^{73,74}

IONM DURING ANTERIOR CERVICAL SPINE SURGERY

Anterior cervical decompression and fusion (ACDF) surgery is one of the most commonly performed spine surgeries and is indicated for treatment of a wide range of pathology. A recent retrospective analysis of 1,015 patients revealed an overall morbidity rate of 19.3%.⁷⁵ In this study, the most common injuries were transient dysphagia (9.3%) and soft tissue hematoma (5.6%). Notably, 3.1% of patients exhibited clinical signs of recurrent laryngeal nerve (RLN) palsy, as evidenced by postoperative vocal cord paralysis. Therefore, ACDF surgery carries risk for RLN injury, particularly when the C7/T1 level is involved⁷⁶ and during reoperations.⁷⁷ While RLN monitoring with spontaneous EMG can provide valuable information about nerve irritation, absence of activity is not a reliable indicator of intact function.^{43,44} Complementing spontaneous EMG, stimulus-triggered EMG can be used to quickly, accurately, and safely identify the RLN and reduce the incidence of injury, allowing the surgeon to proceed with confidence.⁷⁸

Iatrogenic spinal cord or nerve root injury during ACDF surgery is rare, but can occur at a number of points during

the procedure. For example, spinal cord injury can occur as a result of vascular compromise or spinal cord stretch/traction during interbody distraction or graft placement and from spinal cord contusion or laceration during breach of the posterior longitudinal ligament or migration of a graft into the spinal canal. Likewise, nerve root injury can occur as a result of excessive traction during distraction, and contusion/laceration during foraminotomy or release of distraction. TceMEP testing, conducted after significant surgical maneuvers, provides the surgeon with timely warning of evolving injury. Attenuation or loss of all tceMEPs below the level at which the surgeon is working, with preservation of motor responses above that level is usually consistent with acute spinal cord trauma. Somatosensory evoked potentials from the upper and lower extremities can serve as an adjunct in determining the extent of injury to the spinal cord. Attenuation or loss of tceMEPs from a single myotome may indicate insult to a single nerve root.⁷⁹ Free-running EMG can be used as an adjunct to tceMEPs to identify nerve root compression or stretch. When tceMEP changes are not consistent with the level of surgery, the operating room team should investigate peripheral factors, such as positioning-related compression of the arm or hand.

Spine surgery at any segment carries risk for the development of an epidural hematoma, the onset of which may be delayed by some time.^{75,80} Attenuation of tceMEPs can also serve as an early indicator of developing epidural hematoma,⁸¹ giving the surgeon the opportunity to evacuate prior to the end of the procedure, and avoiding reoperation. Thus, it is recommended that the neurophysiologist continue monitoring at least through closure of fascia during cervical spine surgery.

IONM DURING POSTERIOR CERVICAL SPINE SURGERY

Posterior surgery of the cervical spine carries many of the same risks as those associated with anterior approaches, as well as several that are unique to the approach. Intraoperative neurophysiological monitoring changes during posterior laminectomy/laminotomy decompression of the cervical spine can be caused by a number of factors. In some cases, the dura can be particularly adhered to the lamina. Removing the adherent lamina can lead to the sudden release of the tethered dura, which may cause the spinal cord to recoil into the canal, producing acute traction or contusion of the cord. Decompressive laminectomy

of a severely stenotic canal indirectly decompresses the spinal cord allowing it to float away from compressive lesions, sometimes leading to temporary changes in spinal cord perfusion. This can cause biochemical changes to both the intracellular and extracellular environments, which result in transient conduction block.⁸² In this situation, tceMEPs and SSEPs may be abolished or attenuated for several minutes.

Posterior cervical fusion with pedicle and lateral mass screw fixation poses risk to the spinal cord and nerve roots and to the vertebral arteries.⁸³ When a breached screw comes in contact with neural elements, tceMEPs and, to a lesser extent, SSEPs can detect the insult if neural conduction has been altered. When pedicle screws are used, tceMEPs should be tested after each screw placement in order to increase specificity of injury detection. Pedicle screw placement in the cervical spine can be assessed with stimulus-triggered EMG. Djurasovic et al.⁸⁴ demonstrated that a 15 mA stimulus threshold had a sensitivity of 88% and a negative predictive value of 99% for correctly identifying a malpositioned pedicle screw. Additionally, stimulus-triggered EMG testing accurately identified 7 of 11 misplaced screws that were missed on plain radiographs.

Spinal cord tumors are typically treated from the posterior approach. It is not uncommon for tceMEPs and SSEPs to become attenuated or abolished during resection of intramedullary lesions, and additional spinal cord testing using D-wave recordings can provide valuable information that allows the surgeon to maximize tumor resection while preserving function. Following laminectomy, epidural D-wave recording electrodes should be placed both cephalad and caudad to the location of the tumor. A baseline D-wave should be established prior to opening of dura and must be established prior to performing a myelotomy. The D-wave is often robust over the cervical spine, owing to the abundance of corticospinal tract fibers, but may be impossible to record in the high cervical region because of contamination by stimulation artifact. Once the recording electrodes are secured, the surgeon must take great care not to move them during the course of surgery, because this can alter the waveform, potentially resulting in a false alarm.⁸⁵ Unlike myogenic tceMEPs, triggering of D-waves produces little or no patient movement, allowing for uninterrupted monitoring during the course of tumor resection.

The surgeon can take steps to decrease the severity of postoperative morbidity associated with myelotomy by

mapping the dorsal columns to identify the median raphe of the spinal cord and so provide a route of entry that is minimally disruptive. Change or even loss of SSEPs is common in intramedullary surgery and may occur immediately upon myelotomy.⁸⁶ Loss of myogenic tceMEPs should be reported, but the surgeon may proceed with resection in the face of an unchanged D-wave.³¹ Conversely, attenuation of the D-wave amplitude by >50% from baseline has been associated with long-term, if not permanent, motor deficit and warrants immediate surgical attention.^{12,87}

ADDITIONAL IONM CONSIDERATIONS DURING HIGH CERVICAL SPINE SURGERY

Anterior exposure of the high cervical spine (C1-3), whether transnasal, transoral, or through the anterior triangle of the neck, carries significant risk for cranial nerve neurapraxia or neurotmesis secondary to retraction or even blunt dissection through soft tissue.⁸⁸ Iatrogenic injury during high cervical surgery has been reported for the mandibular branch of the facial nerve,⁸⁹ the glossopharyngeal nerve,⁸⁸ the hypoglossal nerve,^{90,91} and the superior laryngeal nerve.⁹⁰ Whenever high anterior cervical spine surgery is planned, it is critical to have a preoperative discussion about potential risk to cranial nerves and the need to employ stimulus-triggered EMG for identification and preservation of cranial nerve function. TceMEP and EMG monitoring can be helpful during decompression of the foramen magnum for Chiari malformation, as well as during resection of intradural lesions, each of which may pose risk to the spinal accessory nerve (CN XI).

Instrumented fusion of the high posterior cervical spine places the brainstem at risk for ischemia secondary to vertebral artery injury (compression, rupture, or vasospasm). Brain stem auditory evoked potentials are sensitive to these changes. When the injury compromises blood flow to the brainstem/basilar artery watershed, waves I-V of the BAEP are abolished bilaterally.⁵⁰ Thus, BAEP testing has been recommended whenever screws are placed above the C3 vertebral level, or whenever there is elevated risk of brainstem ischemia secondary to vertebral artery injury.²³

IONM DURING POSTERIOR THORACIC SPINE SURGERY

The thoracic spine comprises the largest anatomic section of the spine, and the type of monitoring required to assess the neural elements depends on the pathology being treated and the planned surgical approach. The most com-

mon approach to the thoracic spine is from the posterior, and a variety of pathologies may be treated via this route. Iatrogenic neurological injury has been reported to the thoracic spinal cord, the conus medullaris, and spinal nerve roots during thoracic spine surgery.⁹² Lower extremity tceMEPs and SSEPs are used to monitor spinal cord long tract function during these procedures. If the conus medullaris is at risk, spontaneous and stimulated EMG can be used as adjunct modalities, providing additional, real-time information to the surgical team regarding the status of spinal nerve roots. Prepositioning baseline tceMEPs and SSEPs can be recorded for patients who are at increased risk of positioning-related spinal cord injury, including those with unstable spines due to fracture-dislocation, marked kyphotic deformities, myelopathy, or space occupying lesions. Monitoring brachial plexus and upper extremity peripheral nerve function is also of the utmost importance because surgical positioning of the limbs places them at risk during prone procedures.⁹³⁻⁹⁵

Intraoperative injury to the thoracic spinal cord can occur during laminectomy or other decompressive maneuvers, via the same mechanisms encountered during posterior cervical spine procedures. Mechanical injury also can occur secondary to placement of thoracic spinal instrumentation. Thoracic pedicle screws have gained popularity as components of spine constructs in recent years. Unlike hooks and wires, they do not require passage of instrumentation into the spinal canal. However, placing thoracic pedicle screws can be challenging, owing to the variable pedicle morphology and small pedicle diameters in the thoracic spine.⁹⁶ Transcranial electric motor evoked potentials are of value in detecting altered motor conduction in the event of inadvertent screw encroachment into the spinal canal and should be recorded following placement of each screw. The combined use of tceMEP and SSEP tests allows for real-time feedback regarding both motor and sensory conduction of the thoracic spinal cord.

While the practice of using stimulus-triggered EMG to test for medial breaches following placement of lumbar pedicle screws has gained acceptance, this methodology has not gained the same popularity in the thoracic spine. This is due, at least in part, to technical demands associated with obtaining artifact-free data, difficulty in isolating segmentally innervated musculature, and animal studies that highlight the challenges of interpreting results.^{97,98} While some have found value in this technique,^{99,100} consensus threshold criteria have not been established for detection of pedicle breaches.

Perhaps the most common application of IONM in thoracic spine surgery is its use during correction of

coronal or sagittal plane deformities within both the pediatric and adult populations. The inconsistent anatomy encountered in these populations makes the placement of pedicle screws challenging, particularly on the concave side of the deformity, which is more likely to approximate the spinal cord. Following coronal or sagittal correction of the spine, and finalization of instrumentation, multimodality monitoring should continue for a minimum of 20 minutes.^{101,102} Loss or attenuation of IONM signals secondary to vessel constriction and ischemia can develop over time, and the premature conclusion of monitoring could miss ischemic events leading to postoperative paraplegia. Timely elevation of blood pressure, adjustment of correction, or, in some cases, removal of hardware can be effective rescue interventions, as illustrated in Figure 12.1. While it is possible to insert epidural electrodes through a flavectomy to monitor D-waves during deformity correction, this may result in a high percentage of false positives, given that the corticospinal tracts can sometimes rotate away from the recording electrode.⁸⁵

Whereas osseous and epidural thoracic spinal tumors can be approached circumferentially, the approach to intradural and intramedullary tumors is usually from the posterior. Similar to surgery for degenerative processes or instability, the type of monitoring necessary for intradural lesions depends on their location, either cephalad to or approximating the conus medullaris. In addition to monitoring long tract conduction with tceMEPs and SSEPs when lesions approximate the conus medullaris, spontaneous and stimulus-triggered EMG can be used to distinguish neural from non-neural tissue. As in the cervical spine, the dorsal physiological midline can be mapped prior to myelotomy for intramedullary tumors.^{37,103} The D-wave is the gold standard for assessing descending motor conduction for intramedullary tumors; however, it is technically challenging to use this modality for lower thoracic or conus lesions. A sufficient percentage of corticospinal tract fibers must be present to generate this wave, and there must also be a sufficient amount of spinal cord caudal to the lesion to place the epidural recording lead.³¹

IONM DURING ANTERIOR THORACIC SPINE SURGERY

The anterior thoracic spine can be approached either via a sternotomy with the patient supine or via an anterolateral thoracotomy. The modalities monitored will again depend on whether the procedure is cephalad to the conus medullaris or approximating it. The lateral decubitus posi-

tion carries its own risks of peripheral neural compromise. In addition to upper extremity ulnar or median nerve monitoring, it can also be beneficial to monitor the radial nerves bilaterally, as they can be placed at risk for compression.¹⁰⁴ Additionally, care should be taken to pad the lower extremity and relieve pressure on the down side common peroneal nerve. Prophylactic padding or suspension of the fibular head is warranted, and monitoring of the distal peroneal nerve motor and sensory pathways can help to ensure ideal positioning without peripheral neural compromise.¹⁰⁵ With lateral positioning, oftentimes shifts in positioning can occur throughout the procedure that can lead to undue pressure on neurological structures in limbs, which are difficult to visualize due to surgical draping and the position of the patient. Intraoperative neurophysiological monitoring can be of great benefit in this situation providing early detection of evolving peripheral nerve injury.

Thoracic spine surgery in the lateral decubitus position often necessitates the sacrifice of one or more unilateral segmental arteries to gain access to the vertebral column. The T4 through T9 segments of the spinal cord comprise the critical vascular zone, where the cord is particularly vulnerable to ischemia.¹⁰⁶ The artery of Adamkiewicz, the largest of the segmental medullary feeder arteries, can also be encountered between T7 and L4 levels, with a bias for the left side of the cord.¹⁰⁶ There has been a debate as to the clinical significance of ligating segmental vessels during approaches to the thoracic spine, with some groups reporting on the relative safety of ligating multiple vessels^{107,108} and others publishing reports of intraoperative neuromonitoring signal changes and adverse postoperative neurological outcomes.^{109,110} Provocative testing can be carried out prior to ligation to help determine if the absence of particular vessels would elevate the risk of intramedullary ischemia. Segmental vessels may be temporarily occluded for several minutes while both tceMEPs and SSEPs are monitored to determine the effects of the occlusion on neural conduction. This may be particularly helpful in patients undergoing revision surgery, circumferential surgery, a left-sided approach, or those with kyphotic deformity who may be at an elevated risk for neural compromise secondary to a vascular etiology.¹⁰⁹

IONM DURING LUMBOSACRAL SPINE SURGERY

Although most surgeries in the lumbosacral spine do not place the spinal cord at direct risk of injury, IONM has seen increased application in these procedures to protect nerve root function. Depending on the pathology and the

surgical approach, spinal nerve roots can be placed at risk of injury within the thecal sac, as they exit the foramen, and peripherally as they form the lumbosacral plexus and peripheral nerves. There is no consensus on the most appropriate way to monitor these peripheral pathways, and the three “cornerstone” modalities all have their benefits and limitations. Electromyography is perhaps the most commonly utilized IONM modality in this region of the spine. The application of stimulus-triggered EMG as a means of testing medial pedicle cortex integrity following placement of pedicle screws is well established;^{18,111,112} however, the use of spontaneous EMG as a unimodal strategy can yield both high false-positive and high false-negative rates and has poor positive predictive value for adverse postoperative outcomes.⁴⁰

Lower extremity SSEPs are also limited in that they only survey the sensory aspects of the mixed peripheral nerves and the posterior spinal rootlets. Also, fibers from the peripheral nerves most commonly stimulated to elicit SSEPs enter the spine at several levels. Thus, injury to one of these roots may not sufficiently degrade the overall SSEP amplitude, resulting in a false-negative finding. Use of tceMEPs as a means of assessing individual lumbar nerve roots remains controversial due to radicular overlap, trial-by-trial variability, and lack of consensus on alert criteria and anesthetic regimens.²⁸ Despite these limitations, tceMEPs can be a useful component of a multimodality monitoring plan.^{113,114} The potential utility of tceMEPs as an adjunct modality when monitoring in the lumbosacral spine has been shown in a porcine model,^{115,116} and a retrospective intraoperative study,¹¹⁷ which demonstrate the ability of tceMEPs to detect isolated nerve root injury.

IONM DURING POSTERIOR LUMBOSACRAL SPINE SURGERY

As with the thoracic spine, the most common approach to the lumbar spine is from the posterior. Monitoring of the upper extremities, either by SSEPs or tceMEPs, can help to detect impending compression or stretch of the brachial plexus or the peripheral nerves.⁹³ Prepositioning data should be obtained in the face of either an unstable spine or preexisting brachial plexopathy. Iatrogenic injury may occur secondary to decompression, osteotomy, correction of deformity, unintended durotomy, retraction of a nerve root or the thecal sac, placement of instrumentation, place-

ment of interbody graft, tumor resection, or cord untethering.

Recording of triggered EMG to electrical stimulation of pedicle screws has been used successfully for more than two decades to assess the integrity of the medial pedicle wall.^{18,111,118} This threshold technique allows for effective detection of medially malpositioned screws, while limiting the amount of intraoperative and postoperative radiation exposure that would occur with intraoperative O-arm or postoperative CT scan, respectively.¹¹⁹ A limitation of triggered EMG is that it is lacking in ability to detect lateral breaches in pedicle integrity. It is important to note that abnormally high stimulation thresholds may be encountered in the face of chronically compressed nerve roots, or preexisting comorbidities such as neuropathy or myopathy,³⁹ possibly leading to false-negative results. In these situations, nerve roots can be exposed and directly stimulated, thereby establishing a control threshold against which thresholds to screw stimulation can be compared.¹¹¹ High thresholds can also be caused by current shunting through fluid in the surgical field or a retractor in contact with the screw head, drawing current away from the intended pathway, and producing a false-negative result. Meticulous stimulating techniques are always necessary to ensure the accuracy of test results.

Lumbar deformity correction places the spinal nerve roots at an increased risk compared with surgery for degenerative conditions. Iatrogenic injury can occur during screw placement, pedicle subtraction, or correction of kyphosis. Reduction of high-grade spondylolisthesis may subject the spinal nerve roots to stretch, thereby increasing the likelihood of postoperative deficit.^{120,121} Fixed sagittal imbalance can be addressed in the lumbar spine through single or multilevel osteotomy with instrumented correction of kyphosis. Sagittal correction may place neural elements at risk at multiple points, as the spinal cord, spinal nerve roots, and peripheral nerves are all susceptible to stretch with reintroduction of lordosis into the vertebral column. Lieberman et al.¹¹⁷ demonstrated successful identification of lumbar spinal nerve root injury with tceMEPs during correction of fixed sagittal plane deformities, using an alert criterion of >80% amplitude decrease.

Multimodality IONM is also useful in protecting neural function during resection of cauda equina lesions and spinal cord untethering in the dysraphic population.¹¹⁴ Stimulus-triggered EMG is the gold standard for mapping in these procedures, allowing for differentiation of neural from non-neural tissue, as well as sensory from motor fibers.

Fig. 12.3: Transcranial electric motor evoked potential (tceMEP) attenuation during anterolateral transpsoas L3/4 discectomy with interbody fusion for pseudoarthrosis, demonstrating sensitivity to evolving peripheral nerve injury. Transcranial electric motor evoked potentials were of sufficient size and consistency for reliable monitoring at baseline and during the approach through the muscle. Following placement of the retractor, there was a loss of the left-side tceMEPs from iliopsoas and quadriceps myotomes. There was no remarkable spontaneous or stimulus-triggered electromyographic activity during the approach or following retractor placement. Despite removal of the retractors, there was only minimal improvement during the balance of the procedure. Postoperatively, the patient presented with new onset left femoral nerve palsy. (FD: First dorsal interosseous; RA: Rectus abdominis; IP: Iliopsoas; QD: Quadriceps; TA: Tibialis anterior; GA: Gastrocnemius; AH: Abductor hallucis; AN: External anal sphincter; Prefixes L and R indicate the left and right sides, respectively).

IONM DURING ANTERIOR LUMBOSACRAL SPINE SURGERY

Anterior and anterolateral approaches to the lumbar and lumbosacral spine have become increasingly popular in recent years. However, the anterior approach carries its own unique risks, in addition to those described for the posterior approach. Ischemic events can occur secondary to retraction of the aorta, vena cava, or iliac vessels to gain access to the correct spinal levels.¹²² Pulse oximetry of the lower extremities is commonly used to help detect evolving infarction. Lower extremity SSEPs and tceMEPs are also sensitive to ischemia and can serve as an adjunct to pulse oximetry and use of vital signs.^{123,124} Injury to the superior hypogastric plexus can result in sexual dysfunction and retrograde ejaculation in the male population. At present, reliable intraoperative detection of injury to the autonomic nervous system remains a significant monitoring challenge.

The anterolateral, transpsoas approach to the lumbar spine has gained popularity in recent years as an alternative to the supine retroperitoneal approach. The transpsoas approach has the benefit of reducing risk of injury to major vasculature; however, it places the exiting nerve roots and the lumbosacral plexus directly at risk as they pass through the psoas muscle.¹²⁵ In a recent review of the literature and parallel case series, Sofianos and colleagues¹²⁶ reported

a variable rate of complication associated with the transpsoas approach to the spine, with their own series yielding a 40% complication rate. As the psoas muscle is traversed, stimulus-triggered and spontaneous EMG can be used to assess the proximity of dilators and other instruments to neural elements. In addition, tceMEPs can provide valuable information about evolving stretch injury outside the exposed field that might otherwise be missed, as illustrated in Figure 12.3. Likewise, injury to the contralateral nerve roots occurring secondary to discectomy or graft placement may not be detected with EMG alone, pointing to the need for a multimodality monitoring approach during these procedures.¹²⁷

CONCLUSION

Over the past decades, the evolution of IONM has seen it advancing from humble laboratory beginnings as a single test to a comprehensive continuous multimodality strategic analysis of the nervous system. This has made it an invaluable asset in the advancement of the field of spine surgery as a whole, providing monitoring with broad-based coverage of at-risk neural elements. Large prospective, blinded studies of IONM efficacy are lacking in the literature and may never be performed given ethical considerations. There is, however, a growing body of literature pointing to the effectiveness of neuromonitoring in detection of intraoperative neural injury.¹²⁸ Most IONM studies

provide class II or class III evidence of efficacy, which is also true for much of the current practice in neurosurgery.¹²⁹ Timely detection is a key factor in identifying proximate causes of evolving injury, providing effective intervention, and mitigating neurological sequelae. The high sensitivity and specificity of IONM using a multimodality approach have proven its efficacy over the past decades and in many instances have made the need for tests such as the Stagnara wake-up test obsolete. Moving forward, evidence for the utility of IONM will be based on good clinical outcomes, historical controlled studies, and cost-benefit evaluations.¹²⁹ As the spectrum of spine surgery continues to progress into areas such as tumor, trauma, and minimal access surgery, the role of IONM will undoubtedly continue to be integral and invaluable in the care of patients.

KEY POINTS

- The primary goal of IONM is prevention of postoperative neurological sequelae through early intraoperative detection of evolving injury and timely intervention.
- Intraoperative neurophysiological monitoring is based on the premise that neurophysiological activity changes in a measurable and reversible way before the onset of permanent neurological deficit, opening a window of opportunity for correction.
- Intraoperative neurophysiological monitoring carried out by a skilled neurophysiologist is effective in detecting intraoperative neural injury.
- A multimodality IONM strategy, based on careful preoperative assessment of patient and procedure-specific risk factors, is required for comprehensive neurophysiological surveillance during spine surgery.
- Multimodality IONM has found increased application during spine procedures in recent years, both for monitoring functional neural integrity and mapping neural tissue.

KEY REFERENCES

- Devlin VJ, Schwartz DM. Intraoperative neurophysiological monitoring during spinal surgery. *J Am Acad Orthop Surg*. 2007; 15(9):549-60. Review.
- Extensive evidence exists to support the validity of IONM as a tool for identification of emerging neurological injury during spinal surgery. Multimodality monitoring techniques

permit intraoperative assessment of the functional integrity of spinal cord sensory and motor tracts, as well as spinal nerve roots. Combined use of these techniques is useful during complex spinal surgery because these monitoring modalities provide important, complementary information to the surgical team.

- Hilibrand AS, Schwartz DM, Sethuraman V, et al. Comparison of transcranial electric motor and somatosensory evoked potential monitoring during cervical spine surgery. *J Bone Joint Surg Am*. 2004;86-A(6):1248-53.

TceMEP monitoring is superior to SSEP monitoring for identifying evolving motor tract injury during cervical spine surgery, as evidenced by the finding that tceMEPs were 100% sensitive and 100% specific, whereas SSEPs were 25% sensitive and 100% specific. Surgeons should strongly consider using tceMEP monitoring when operating on patients with cervical spondylotic myelopathy, in general, and on those with ossification of the posterior longitudinal ligament, in particular.

- Ahn H, Fehlings MG. Prevention, identification, and treatment of perioperative spinal cord injury. *Neurosurg Focus*. 2008; 25(5):E15. Review.

The authors recommend evidence-based approaches to minimize the chance of perioperative spinal cord injury and to optimize outcome in the event of an injury. A systematic review of the literature focuses on the pathophysiology of spinal cord injury, and options for prevention and treatment are outlined.

- Isley MR, Zhang XF, Balzer JR, et al. Current trends in pedicle screw stimulation techniques: lumbosacral, thoracic, and cervical levels. *Neurodiagn J*. 2012;52(2):100-75.

Stimulus-triggered EMG has been well recognized for improving both the accuracy and safety of pedicle screw implantation. The authors thoroughly reviewed historical events, IONM modalities, alarm criteria, clinical efficacy, current trends, and caveats related to pedicle screw stimulation along the entire vertebral column.

- Nuwer MR, Emerson RG, Galloway G, et al. Evidence-based guideline update: intraoperative spinal monitoring with somatosensory and transcranial electrical motor evoked potentials. *J Clin Neurophysiol*. 2012;29(1):101-8.

The authors review class I and II studies to evaluate whether IONM with SSEPs and/or tceMEPs predicts adverse surgical outcomes. All studies reported that paraparesis, paraplegia, and quadriplegia occurred in the face of evoked potential (EP) changes, with no occurrences in the absence of EP changes. The authors state that IONM is established as effective to predict an increased risk of adverse outcomes in spinal surgery and conclude that members of the operating team should be alerted to these risks in patients with important IONM changes.

Anesthesia and Perioperative Care of Patients for Spine Surgery

Snapshot

- » Preoperative Evaluation and Optimization of the Patient for Elective Spine Surgery

INTRODUCTION

Surgery on the spine encompasses a broad spectrum of elective and emergency procedures with vastly different considerations. Spine surgery procedures may be performed in a day surgery setting or they may involve complex, staged operations performed over multiple days with the attendant fluid shifts, blood loss, and potential for multi-organ dysfunction. Preoperative identification and optimization of comorbidities coupled with appropriate management throughout the perioperative period is paramount for patients undergoing spine surgery. In this chapter an anesthesiologist's approach to perioperative evaluation, optimization, and management of the spine surgery patient is presented. In addition, the management of medical complications of spinal cord injury (SCI), bleeding and clotting complications, options for pain management, and managing complications uniquely associated with spine surgery are discussed.

PREOPERATIVE EVALUATION AND OPTIMIZATION OF THE PATIENT FOR ELECTIVE SPINE SURGERY

Cardiovascular System

Cardiovascular complications are among the most common following surgery and are associated with significant morbidity and mortality.¹ The American College of Cardiology/American Heart Association (ACC/AHA) published

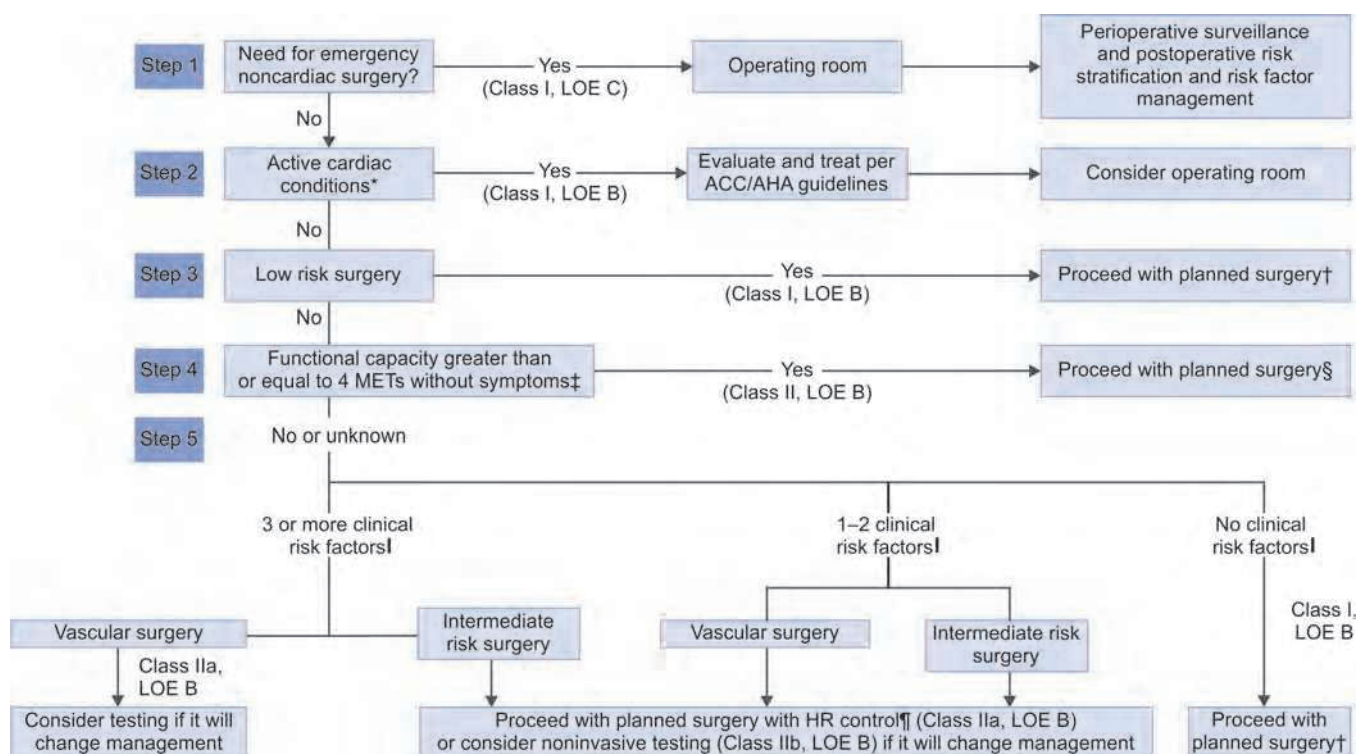

guidelines on perioperative cardiovascular evaluation and care for patients undergoing noncardiac surgery to help reduce perioperative morbidity and mortality from cardiovascular events.²

The AHA/ACC guidelines follow a stepwise and algorithmic approach that begins with determining the urgency of surgery (Flowchart 13.1). Patients who require emergency surgery should proceed to the operating room with baseline investigations and optimization performed as time and the patient's condition allow (class 1, level of evidence: C). Intraoperative management may be modified, and further surveillance and management of cardiovascular disorders is undertaken after surgery.

When surgery is not emergent, patients are evaluated for "active" cardiac conditions: unstable coronary syndromes, decompensated heart failure, significant dysrhythmias, or severe valvular disease. The benefit of optimizing these conditions should be considered against the risk of delaying surgery. Patients with active cardiac conditions should undergo evaluation and possibly treatment before noncardiac surgery (class I, level of evidence: B). Appropriate management of an active condition is required regardless of the need for surgery. An important caveat is that decisions to offer interventions (such as revascularization in patients with coronary artery disease) are made independent of the imminent proposed surgery.

Most spine surgery is considered intermediate risk with expected adverse cardiac event rates of 1–5% (cardiac death and nonfatal myocardial infarction). For intermediate risk surgery, functional capacity and patient risk

Flowchart 13.1: Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or greater.

(ACC/AHA: The American College of Cardiology/American Heart Association; LOE: Level of Evidence; METs: Metabolic equivalent tasks).

* Active cardiac conditions: Unstable coronary syndromes, decompensated heart failure, significant arrhythmias, and severe valvular heart disease.

† Noninvasive testing is not useful for patients with no clinical risk factors undergoing intermediate-risk and low-risk noncardiac surgery. (Level of Evidence: C)

‡ 4 METs (metabolic equivalent task) includes the ability to climb a flight of stairs or walk up a hill

§ Noninvasive testing may be considered before surgery in specific patients with risk factors if it will change management.

I Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease.

¶ If the patient has 1 or 2 clinical risk factors, then it is reasonable to either proceed with the planned surgery, with heart rate control with beta blockade (controversial), or consider testing if it will change management.

Source: Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guideline.) *Circulation*. 2007;116:e418-99.

factors determine need for further investigations. Functional capacity is often described in terms of metabolic equivalent tasks (METs): one MET is oxygen required for basal metabolic function. Patients who can complete four METs (climbing a flight of stairs or walking up a hill) without symptoms can proceed to surgery (class IIa, level of evidence: B). Functional assessment is often limited as many patients for spinal surgery cannot exercise due to pain or disability from their spinal condition. The Revised Cardiac Risk Index (RCRI) identifies five independent risk correlates (besides high-risk surgery): stable ischemic heart disease, controlled or prior congestive heart failure, cerebro-

vascular disease (history of stroke or transient ischemic attack), insulin-requiring diabetes, and renal insufficiency.³ Patients with poor functional capacity or who are limited by pain or disability to less than four METs and who have RCRI risk factors should be investigated further if this will change the perioperative management of the patient (class IIb, level of evidence: B). Options for noninvasive testing for coronary artery disease in patients who are unable to exercise include radionuclide myocardial perfusion imaging and dobutamine stress echocardiography, the latter having slightly better diagnostic performance.⁴

Antiplatelet Agents

Aspirin, also known as acetylsalicylic acid (ASA) and clopidogrel are used for primary and secondary prevention of patients with cardiovascular disease (including those with coronary stents). Historically, these drugs are discontinued 7 days or more before surgery due to concerns about risk of perioperative bleeding. Recently this practice has been questioned as it may increase the risk of postoperative cardiovascular morbidity and mortality.⁵

In a retrospective review of 244 patients undergoing spinal instrumentation and fusion, there was no increase in bleeding or transfusion in patients taking ASA.⁶ In their review of perioperative antiplatelet therapy, Chassot et al. acknowledge that while prospective studies with high degree of evidence are lacking, the increased bleeding risk associated with continuing ASA throughout the perioperative period may be outweighed by the greater risk of coronary thrombosis with significant morbidity and mortality.⁷ Although surgery in an enclosed space such as intracranial neurosurgery or intramedullary canal surgery could be considered an exception, Chassot contends that ASA should never be stopped when prescribed for secondary prevention of cerebrovascular and cardiovascular conditions. When ASA is used as primary prevention, it may be withdrawn but no more than 7 days before surgery. Elective surgery may be inadvisable in patients on clopidogrel or dual therapy, and direction from hematology or cardiology is required. Antiplatelet agents should be resumed as soon as possible after surgery when the risk of postoperative bleeding has diminished.⁸

Intraoperative Management of Patients at Risk for Cardiovascular Complications

Patients at risk for cardiovascular complications may require more intensive ischemia and blood pressure monitoring, have a lower tolerance for blood pressure and heart rate fluctuations, and require a higher transfusion threshold.^{2,9} The decision to include arterial and central venous monitoring is based on patient comorbidities and surgical factors such as extent of cardiovascular disease, duration of surgery, potential need for vasoactive drugs, and an anticipation of significant blood loss. Noninvasive cardiac output monitors may be considered to help guide fluid resuscitation and use of vasoactive drugs.^{10,11} Postoperative surveillance in susceptible patients is critical for early recognition and management of ischemia.²

Cardiovascular Management in Spinal Cord Injury

Management of the cardiovascular complications of the patient with acute SCI requires knowledge of the pathophysiology of this condition. The goal when resuscitating a patient with SCI is to prevent secondary injury by ensuring adequate oxygen delivery to the spinal cord. Hypotension following SCI is common, although various definitions for hypotension have been used. In an observational study by Levi and colleagues, systolic blood pressure (SBP) <90 mm Hg on admission was present in 8 of 50 (16%) of patients admitted with SCI. This proportion was higher in patients presenting with quadriplegia (7 of 31, 26%).¹² Another observational cohort of patients admitted with isolated complete SCI demonstrated a progressive increased proportion of patients with hypotension with a more cephalad injury. In this cohort, SBP <100 mm Hg occurred in 70 of 301 (26%) of complete cervical SCI, compared with 16 of 155 (12%) with thoracic and 1 of 34 (3%) with complete lumbar injuries, respectively.¹³ Patients with SCI are predisposed to hypotension from multiple causes including neurogenic shock, hypovolemia from hemorrhage, and obstructive or cardiogenic shock from major cardiothoracic trauma.

The mechanisms behind neurogenic shock are well characterized.¹⁴ Damage to the autonomic nervous system in SCI causes decreased sympathetic outflow leading to decreased vasomotor tone and reduction in systemic vascular resistance. Spinal cord injury at T6 results in decreased outflow from the sympathetically mediated cardiac accelerator fibers causing a decrease in heart rate and decrease in contractility. Parasympathetic innervation to the heart remains intact resulting in imbalance, severe bradycardia, and decreased contractility. Long-term autonomic dysfunction from severe SCI leads to orthostatic hypotension and autonomic dysreflexia.¹⁴

The American Association of Neurological Surgeons/Congress of Neurological Surgeons recommend that a mean arterial pressure of 85–90 mm Hg be maintained for the first 7 days following acute SCI.¹⁵ Clinical practice guideline from the Consortium for Spinal Cord Medicine also recommends prevention and treatment of hypotension using fluids and vasopressors to maintain an MAP of 85 mm Hg for 7 days.¹⁶ The clinical evidence supporting this recommendation is weak, consisting of uncontrolled observational studies.^{12,17} In patients suffering from traumatic brain injury (TBI), SBP <90 mm Hg has been consistently associated with worse long-term outcomes,¹⁸

and therefore maintenance of cerebral perfusion pressure has become a cornerstone in the critical care management of TBI.¹⁹ Given this intervention is reasonably well tolerated, combined with strong biologic rationale, it seems prudent to maintain spinal cord perfusion using MAP goals recommended above. Adequate volume repletion with appropriate fluids, titrated vasopressor therapy with either norepinephrine or dopamine (the latter in patients with bradycardia), and early arterial pressure monitoring and central venous access are crucial to optimize spinal cord perfusion in acute SCI.

Respiratory System

As with cardiovascular system risk assessment, determination of risk for postoperative pulmonary complications (PPCs) guides perioperative management and may reduce complications.^{20,21} Optimization of respiratory conditions requires identification of modifiable risk factors and provision of appropriate treatment, which is usually indicated regardless of the need for surgery. Both surgical and patient factors impact perioperative pulmonary risk assessment.

The incidence of PPCs is high, and PPCs are associated with perioperative morbidity and mortality. Pulmonary complications may be the most important factors increasing hospital stay and costs.^{22,23} Pulmonary complications include atelectasis, bronchitis and pneumonia, bronchospasm, and exacerbation of underlying lung disease as well as respiratory failure.²⁴ In a multivariable cohort analysis, Lee et al. found PPCs to be independently associated with death within 2 years in patients undergoing lumbar spine surgery.²⁵ Using the American College of Surgeons National Surgical Quality Improvement Program data set, Gupta et al. demonstrated the risk of postoperative respiratory failure (failure to wean from mechanical ventilation within 48 hours of surgery or unplanned intubation/reintubation postoperatively) occurred in 3.1% of patients undergoing a variety of procedures in both community and academic centers.²⁶ Twenty-five percent of patients with postoperative respiratory failure died within 30 days.

The American College of Physicians guidelines identify patient-specific risk factors for PPCs: chronic obstructive pulmonary disease (COPD), advanced age, American Society of Anesthesiologists classification of 2 or higher, functional dependence, and congestive heart failure.²⁷ In a prospective multicenter cohort study, Canet et al. also demonstrated that a low preoperative arterial oxygen saturation, acute respiratory infection during the previous month,

and preoperative anemia to be risk factors for PPCs.²⁸ Additional patient factors include smoking, obesity, obstructive sleep apnea (OSA), and pulmonary hypertension.²⁹ Emergency procedures, prolonged surgery (>3 hours), and operations proximate to the diaphragm increase the risk of PPCs.³⁰ In their analysis of medical complications following lumbar spine surgery, Lee et al. found the invasiveness of the procedure to be one of the highest predictors.²⁵

Tobacco smoking is a consistent risk factor for perioperative respiratory, cardiovascular, and wound healing complications following surgery.^{31,32} Smoking cessation is of particular importance for successful spine fusion surgery,³³⁻³⁵ and some centers performing spine fusion measure urine nicotine levels preoperatively and decline patients who continue to smoke.³⁶ Major surgery may be an opportunity to facilitate smoking cessation.³¹ However, despite effective interventions,³⁷ clinicians do not consistently counsel patients on the importance of smoking cessation.³²

Chronic obstructive pulmonary disease is a common and important risk factor associated with perioperative respiratory complications.³⁸ Elective surgery should be postponed during an exacerbation of COPD, and treatment with antibiotics and steroids instituted to achieve the best possible level of pulmonary function preoperatively. Perioperative administration of inhaled beta agonists and anticholinergics are indicated in patients responsive to their bronchodilating effects.²¹ Patients with well-controlled asthma seem to have no increased complication rates associated with surgery,³⁹ although severe bronchospasm may occur associated with general anesthesia where asthma is poorly controlled.⁴⁰

Obstructive sleep apnea is associated with increased PPC and potential difficult airway management.⁴¹ The American Society of Anesthesiologists recommends preoperative surveillance for OSA to identify patients and initiate continuous positive airway pressure (CPAP) therapy before surgery in severe cases.⁴² Postoperative management of OSA includes resuming CPAP early, careful titration of respiratory depressant medications, and appropriate monitoring during recovery from surgery.

Deep breathing and cough, incentive spirometry, intermittent positive pressure breathing, and CPAP are effective in preventing PPCs.⁴³⁻⁴⁵ Patient effort is critical in these lung expansion techniques, which are best taught prior to surgery, and appropriate analgesia facilitates postoperative respiratory therapy. Preoperative inspiratory muscle training reduces PPC in patients having cardiac and abdominal surgery.^{46,47} Intraoperative measures to reduce PPC

include intubating with modified endotracheal tubes in patients expected to require mechanical ventilation after surgery. These tubes allow subglottic secretion drainage and reduce the incidence of ventilator-associated pneumonia.⁴⁸⁻⁵⁰ Low tidal volume (6–8 mL/kg) ventilation may be associated with improved clinical outcome even in patients without adult respiratory distress syndrome.⁵¹ Intraoperative placement of postpyloric feeding tubes where prolonged postoperative intubation is possible or where swallowing is predicted to be impaired such as following anterior cervical surgery may protect from aspiration and allow early feeding.⁵²

Respiratory Management in SCI

Respiratory failure necessitating intubation and ventilation is common following acute cervical SCI especially in patients with complete cervical injuries⁵³ and injuries at the C5 level or above^{54,55} in whom phrenic nerve and diaphragmatic dysfunction lead to reduced tidal volumes and vital capacity.⁵⁶ Observational studies show that intubation will be required in 69–88% of patients with SCI at C5 or above.^{57,58} While diaphragmatic function is preserved in lower cervical spine injuries, intercostal muscle paralysis results in chest wall indrawing during inspiration and ventilatory dysfunction.⁵⁶ Impaired cough from abdominal muscle paralysis reduces clearance of secretions leading to mucous plugging and increased risk of pneumonia.

The decision to intubate is often based on multiple factors and requires judgment of the clinician. These patients require monitoring in a high acuity environment and, although no firm intubation criteria exist, it should be considered when signs of fatigue become apparent. Vital capacity can be followed over time and intubation considered once vital capacity becomes <15 cc/kg.⁵⁹ Airway instrumentation may lead to secondary SCI as intubation can result in cervical spine movement. Although direct laryngoscopy results in movement of the cervical spine,⁶⁰ when combined with manual in-line stabilization it remains a reasonable option, particularly in patients who are either uncooperative or require immediate intubation. Survey data demonstrate that anesthesiologists prefer to use a spontaneous breathing technique with fiberoptic bronchoscopy.⁶¹ This technique has several advantages: the neck is maintained in neutral position minimizing spine movement with excellent glottic visualization, and a neurologic examination following intubation assures no secondary damage has occurred.

The majority of patients with cervical SCI will liberate from mechanical ventilation provided diaphragmatic function remains intact. Tracheostomy may be used to facilitate liberation and has several advantages including decreased airway resistance, thereby reducing respiratory work and greater patient comfort than endotracheal intubation. Tracheostomy may reduce the risk hospital-acquired pneumonia⁶² and reduce days free of ventilation and intensive care.⁶³

Renal Management

Perioperative renal management centers on preserving function and preventing injury. The incidence of perioperative acute kidney injury (AKI) in spine surgery is unknown. In a prospective observational study, risk factors for AKI in noncardiac surgery patients with normal preoperative renal function were age, emergent surgery, liver disease, body mass index, high-risk surgery, peripheral vascular occlusive disease, and COPD requiring chronic bronchodilator therapy.⁶⁴ In the same study, intraoperative total vasopressor dose, use of vasopressor infusion, and diuretic administration were independent predictors of renal failure, which occurred in 0.8% of patients. In patients undergoing major surgery, Abelha et al. found similar predictors for AKI as well as American Society of Anesthesiologists physical status, coronary artery disease, and RCRI score in patients with previously normal renal function who required intensive care following surgery.⁶⁵

Although no specific interventions have been shown to prevent AKI, maintaining renal perfusion is paramount given association of AKI with hypotension, diuretic use, and bleeding requiring transfusion.⁶⁶ Avoiding angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists prior to surgery may be advisable, especially when hypotension is anticipated.⁶⁷ Other elements of perioperative care may affect AKI such as use of synthetic colloids, which increase the risk of AKI in lung resection surgery⁶⁸ and patients with sepsis.⁶⁹

Blood and Coagulation Management

Risks of blood product transfusion include acute hemolytic reaction, transfusion-related acute lung injury, bacterial and viral infections, and transfusion-related immunomodulation. Transfusion-related immunomodulation is associated with increased postoperative infection,⁷⁰ length of hospital stay, and possibly cancer recurrence.⁷¹ The decision to transfuse must be weighed against the risks of anemia and coagulopathy.

Preoperative anemia is common; one Canadian institution found an incidence of 40% in elective surgical patients.⁷² In this study, anemia was an independent predictor of 90-day mortality, and anemic patients were more likely to require transfusion. Many hospitals now have blood management programs that target patients having surgery with high transfusion rates, such as major spine surgery. These programs identify, optimize, and treat patients with preoperative anemia and further make recommendations on intraoperative red blood cell conservation. Patients are ideally referred to the program when first assessed for surgery, allowing adequate time for management. Options for preoperative management include iron supplementation, erythropoietin, and autologous donation. Intraoperative recommendations may include use of antifibrinolytics, cell salvage, and acute normovolemic hemodilution (ANH).

Preoperative Management

Iron replacement is recommended when deficiency exists. Oral iron replacement may be sufficient if there is adequate preoperative time prior to surgery (>2 months). In cases where there is insufficient time prior to surgery, poor response to oral iron, and cases of intolerance to oral Fe, parenteral Fe is recommended. Erythropoietin may be used, particularly in patients who refuse blood products, where there has been an inadequate response to iron therapy and to improve hemoglobin recovery in patients donating autologous blood.

Preoperative autologous blood donation may be offered to patients wishing to avoid allogeneic blood. One to three units of blood can be drawn preoperatively at 1-week intervals and returned during surgery. Risks of autologous blood include clerical error and bacterial infection. The transfusion trigger should be the same as for allogeneic blood, and collected units may thus be discarded. Patients may have inadequate recovery of hemoglobin, resulting in preoperative anemia and blood may outdate should the operative date be postponed.⁷³

Intraoperative Management

Antifibrinolytic medications (tranexamic acid and epsilon-aminocaproic acid) block the activation of plasminogen to plasmin and are routinely used in major spine surgery.^{74,75} The fibrinolytic system is activated during surgery, resulting in breakdown of preexisting clot and secondary bleeding.

Cell salvage is the most effective blood-saving technique available.⁷⁶ Shed blood is aspirated from the wound, mixed with anticoagulant and filtered into a reservoir, washed, and returned to the patient. Red blood cells obtained from cell salvage are free from platelets and clotting factors, which are removed during the process. This can lead to dilutional coagulopathy. Limiting suction pressures, turbulent flow in the field, and allowing blood to pool as much as possible before collection will minimize damage of red cells and maximize recovery. The majority of patients refusing red cell transfusion will accept cell salvage. Cell salvage has been considered contraindicated in cases of infection or cancer, although the concern of cancer spread has recently been questioned, particularly with the use of leukocyte reduction filters.⁷⁷

Acute normovolemic hemodilution involves blood collection in the operation room prior to blood loss and subsequent volume replacement with crystalloids or colloid. Because fresh whole blood obtained through ANH contains platelets and clotting factors, the risk of dilutional coagulopathy is mitigated, although the clinical benefits of ANH remain unclear.⁷⁸ The majority of patients refusing blood products will accept ANH.

Intraoperative management of volume status involves ongoing assessment of blood loss, laboratory testing, and appropriate fluid management including transfusion when necessary. When blood loss is significant, serial hemoglobin and coagulation parameters are measured. Transfusion trigger for red cells is generally considered to be between 60 and 80 g/L with a higher trigger in patients with ischemic heart disease and when blood loss is large and ongoing.⁹ Cryoprecipitate may be used when fibrinogen is low despite administration of plasma. Activated Factor VIIa is considered in rare circumstances of microvascular bleeding despite replacement of clotting factors,⁷⁹ and fibrinogen concentrates may also show promise in this situation.⁸⁰

Venous Thromboembolism Prophylaxis

Venous thromboembolism (VTE) is a common and preventable cause of death in hospital.⁸¹ There are approximately 200,000 deaths related to VTE per year in the United States with trauma and the postoperative period being significant risk factors.⁸² With regard to spine surgery, there are two broad populations to consider: patients with spine trauma or SCI and those undergoing nontrauma surgery.

Patients with spine trauma have a high risk of VTE with a baseline risk of 2.2% increasing to 5–6% in those patients with SCI.⁸³ The American College of Chest Physicians (ACCP) guidelines recommend patients with spinal trauma or SCI receive pharmacologic prophylaxis with either low-dose unfractionated heparin (grade 2 C) or low molecular weight heparin (LMWH) (grade 2 C). They further recommend that mechanical prophylaxis with intermittent pneumatic compression devices be added provided no contraindication to these devices exists (grade 2 C).⁸³ Finally, an inferior vena cava filter should not be used as primary prophylaxis.

The recommendations for VTE prophylaxis are less clear in patients undergoing nontrauma spine surgery where the benefit of pharmacologic prophylaxis must be weighed against the risk of postoperative hemorrhage. In this population, the baseline risk for VTE is very low. A retrospective review of 1,919 patients who all received LMWH demonstrated a risk of VTE of 0.05%. In this cohort, major postoperative hemorrhage attributable to LMWH occurred in 8 of 1,949 patients (0.4%).⁸⁴ Further surgical and patient factors may increase VTE risk including combined anterior-posterior approach, multiple operative levels, older age, prior VTE, and malignancy.⁸³ The ACCP guidelines recommend intermittent pneumatic compression devices be used for all patients undergoing spinal surgery (grade 2 C). For patients with high risk of VTE (as listed above), pharmacologic prophylaxis should be added to mechanical prophylaxis once hemostasis is achieved and the risk of postoperative hemorrhage decreases (grade 2 C).⁸³ Similar recommendations are advocated by the North American Spine Society.⁸⁵ There is no good evidence for the timing of these interventions. Intermittent pneumatic compression devices can be instituted at the beginning of the operation. North American Spine Society, based on weak evidence, recommended that when indicated LMWH could be started safely on the elective day of surgery. Because of the preventable morbidity and costs association with VTE, the Agency for Healthcare Research and Quality suggests that a VTE protocol be designed and implemented within an institution to improve rates of VTE prophylaxis.⁸¹

Pain Management in Spine Surgery

Pain management of patients presenting for spine surgery is a challenge for the anesthesiologist and surgeon for many reasons. Patients often have severe back pain or

radiculopathy preoperatively, and the severity of preoperative pain predicts postoperative pain severity, both of which predict higher probability of chronic postsurgical pain. Patients may be disabled and deconditioned by preexisting pain and they are often opioid tolerant.

Patients coming to surgery with high levels of preoperative pain can have a highly sensitized central nervous system (CNS). This makes management of their perioperative pain a challenge because pain can be amplified (hyperalgesia), nonpainful stimuli such as simple movements or light touch can become painful (allodynia) and pain can spread to noninjured tissue. Conventional simple analgesics and opioids may be less effective in the presence of a sensitized CNS, requiring higher doses and more analgesic agents for effective pain management. Preoperative opioid tolerance in itself can sensitize the CNS and cause amplified pain signals postoperatively, leading to increased postoperative consumption of analgesics and a positive feedback loop.

The nociceptive input of major spine surgery is more complex than many other surgeries. Large incisions crossing numerous dermatomes result in activation of peripheral nociceptors and cause extensive inflammation. Pain of musculoskeletal origin results from surgical manipulation of bones, muscles, ligaments, disks, and facet joints. Of all the deep somatic structures, the periosteum has the lowest threshold for pain transmission. Richly innervated periarticular tissues give rise to constant deep somatic pain, which results in severe reflex spasms of muscles supplied by the same or adjacent spinal cord segments.

Pain due to damage or compression of nerve tissue results in intense acute pain postoperatively. Poorly managed analgesia causes patient discomfort, a reluctance to mobilize, and delays discharge. Other complications are related to an exaggerated stress response and can include cardiovascular stress and complications, hyperglycemia, and delayed wound healing and infection. If left untreated, inflammation of nervous tissue initiates a cascade of biological events, sensitizing nerves peripherally and resulting in persistent CNS changes. The incidence of developing chronic pain after major surgery is estimated to be between 20% and 50%, and there is a correlation between the duration of acute postoperative pain and the incidence of persistent postsurgical pain.⁸⁶ The overall severity of pain over the first 7 days is a better predictor of developing a persistent pain state than the maximum pain score reported.^{86–88} Given the strong association between

preoperative pain, postoperative pain, and chronic postsurgical pain, good perioperative analgesia throughout the healing period beyond discharge from acute care is crucial.

Advances in understanding of the pain transmission pathway have lead to a multimodal approach to analgesia in spine surgery. Multimodal or mechanistic analgesia incorporates both opiate and nonopiate analgesics in the treatment of pain. Analgesics with differing mechanisms of action act synergistically to enhance analgesic efficacy, limit the dose of any particular medication, and thereby reduce dose-related adverse effects of these drugs while enhancing patient safety and satisfaction.^{88,89}

Analgesia management begins in the preoperative period with a thorough assessment and establishment of an analgesic plan tailored to the patient's pre-existing pain condition and the magnitude of the surgery. A subjective assessment of the intensity, quality, and timing of the patient's pain along with a functional assessment, including effects on sleep, activity, and mood, is important. The type, timing, and dosage of analgesic medications should be elicited. Patients taking opiates for a period of >4 weeks are prone to developing both tolerance and opioid-induced hyperalgesia, although there is significant patient-to-patient variability.⁹⁰ A history of adverse effects and intolerance to specific medications should be documented. Analgesics should be continued up until and including the day of surgery including sustained release and transdermal opiate formulations in order to prevent withdrawal.

Nonopioid analgesics are important contributors to the analgesic management. Acetaminophen is a synthetic, central acting analgesic that is recommended for the treatment of mild to moderate acute or chronic pain, which has been shown to decrease postoperative opioid requirements and lower pain scores in patients undergoing major orthopedic surgery.⁹¹ The main concern with acetaminophen is hepatic toxicity, which can occur with even minor overdoses.

Nonsteroidal anti-inflammatory agents (NSAIDs) block the peripheral transduction of noxious stimuli at the site of injury by inhibiting the arachidonic acid-cyclooxygenase (COX) pathways. There are two distinct isoforms of COX: COX-1 and COX-2. Cyclooxygenase-1 also has a role in platelet aggregation, gastric protection, and renal blood flow. Cyclooxygenase-2 expression is minimal at baseline and is upregulated with tissue injury.^{92,93}

Both nonspecific NSAIDs and selective COX-2 inhibitors have been studied in spine surgery. A recent meta-

analysis found the addition of NSAIDs to opioid analgesia to be superior to opioid treatment alone for patients undergoing nonfusion lumbar spine surgery.⁹⁴ Paracetamol, a COX-2 inhibitor, was found to be an effective adjunct to patient-controlled morphine in lumbar spine surgery. Patients who received paracetamol had lower pain scores and less morphine consumption.⁹⁵

The routine use of NSAIDs in spine surgery is controversial due to potential impairment of bone healing in patients receiving these drugs.^{96,97} The mechanism by which NSAIDs adversely affect bone ossification is not entirely clear. Prostaglandins play a pivotal role in the bone healing process, and NSAIDs exert their effects through inhibition of prostaglandin synthesis and reduction of the inflammatory response.⁹⁸⁻¹⁰⁰ A recent meta-analysis of retrospective studies looking at failed spinal fusion in patients exposed to NSAID therapy perioperatively revealed normal doses of both NSAIDs and COX-2 inhibitors in the short-term (<14 days) was not associated with failed spinal fusion. Exposure to higher, nonconventional doses of ketorolac was associated with an increased chance of nonunion. The effect of NSAIDs on bone healing may be dose dependent, and further study is needed to examine the safety of longer term exposure to NSAIDs and spinal fusion outcome.¹⁰¹

Gabapentin and pregabalin are neuromodulating medications that show promise in multimodal analgesic management of spine surgery. These medications act via the alpha-2 delta subunit of voltage-dependent calcium channels in the dorsal horn of the spinal cord and brain resulting in a decreased release of excitatory neurotransmitters, which would otherwise amplify the nociceptive pathway.¹⁰² Preoperative gabapentin improves analgesia and decreases opioid consumption in the immediate postoperative period.^{103,104} Pregabalin 150 mg pre- and postoperatively reduced opioid consumption in patients undergoing spinal fusion.¹⁰⁵ In another study, patients receiving pregabalin prior to spinal decompression surgery had improved quality of life up to 3 months following surgery.¹⁰⁶ Somnolence is a common side effect of both medications that needs to be considered and can limit their use perioperatively.

Ketamine is a nonselective *N*-methyl-D-aspartate receptor antagonist. *N*-methyl-D-aspartate receptor activation causes constant neural firing resulting in a "wind-up" phenomenon contributing to central sensitization in which altered neural pathways potentially lead to a persistent

pain state. Ketamine potentiates opioid-mediated analgesia and provides a significant opioid sparing effect.^{107,108} In a study of 26 opioid-tolerant patients undergoing spinal fusion surgery, patients receiving ketamine had significantly lower pain scores for the first 24 hours postoperatively, improved analgesia with physiotherapy, and consumed significantly less patient-controlled analgesia (PCA) hydromorphone compared with placebo.¹⁰⁹ The utility of ketamine in opioid-dependent patients undergoing major lumbar spine surgery was supported in a subsequent study.¹¹⁰ An intraoperative load and postoperative infusion of ketamine should be considered in opioid-tolerant patients coming for major spine surgery and may improve analgesia in these challenging patients.

Opioid medications remain the foundation of analgesia in spine surgery. In the preoperative period, the patient's usual opioids are continued up to the day of the surgery. Intraoperatively, intravenous opioids are administered to provide good initial postoperative pain control. For larger procedures involving multisegmental fusions, techniques such as intravenous opioid PCA combined with other medications, or neuraxial opioid and local anesthetic are used. In most cases, patients will be transitioned to oral opioids within 2–5 days postoperatively. Side effects of opioids are not insignificant and include constipation, nausea and vomiting, urinary retention, itching, and respiratory depression. Combining opioids with nonopioid analgesics will result in a lower overall opioid dose and can minimize these adverse effects.

The use of neuraxial analgesia in spine surgery has been extensively investigated and both spinal and epidural analgesia techniques with local anesthetics and opioids have been used. Studies using a combination of local anesthesia and opioids infused continuously through a surgically placed epidural catheter for spinal fusion surgery have shown inconsistent results.¹¹¹ The use of intrathecal opioid analgesia for spine surgery has been found to be an effective modality in the immediate postoperative period; however, there is no support for long-term benefit and there tends to be an increase in unwanted adverse events such as respiratory depression and pruritis.¹¹¹ Overall, studies have not supported the routine use of neuraxial analgesia outside of scoliosis correction. In studies examining the use of epidural analgesia for both posterior and anterior approaches to scoliosis correction, patients who received a surgically placed epidural experienced better postoperative analgesia, earlier return of bowel function, fewer side effects, and higher patient satisfac-

tion.^{112,113} A meta-analysis examining the use of epidural analgesia for adolescent patients undergoing scoliosis correction demonstrated lower pain scores in the epidural group at 24, 48, and 72 hours following surgery.¹¹⁴

Complications during Spine Surgery

Air Embolism

Entrainment of air via open venous channels leading to air embolism is classically associated with the sitting position for surgery where the vertical distance between open venous channels at the operative site and the central circulation is increased. Depending on the venous pressure, a positive pressure gradient exists between the atmosphere and the central venous compartment. There are several reports of venous air embolism (VAE) verified at autopsy in surgery in the prone position,¹¹⁵ and it has been postulated that VAE is underreported in spine surgery.¹¹⁶

Risk factors for VAE in spine surgery include major blood loss and hypovolemia, hip and knee flexion,^{117,118} and spontaneous ventilation. Patients with an atrial septal defect are at risk for systemic air embolism through right to left shunting. Autopsy evidence of intracoronary and intracerebral air has also been demonstrated to occur even in the absence of anatomic shunts.¹¹⁵

Monitoring for VAE and its treatment can take many forms. Clinical features of VAE include a precipitous drop in end-tidal carbon dioxide, often accompanied by hypotension and other indicators of diminished cardiac output. Air entrainment can be identified using precordial Doppler, stethoscope, or ultrasound. Treatment of VAE consists of simultaneously stopping further entrainment of air, facilitating clearance of air already entrained, and supporting the circulation. Flooding the field with saline and obstructing venous channels stop further entrainment of air. Intravascular volume expansion and vasopressor administration increases central venous pressure (CVP), reduces further entrainment, and provides circulatory support. Although left lateral and head down position can theoretically attenuate flow of air via the pulmonary outflow tract, this position can be impractical in the prone patient. Early chest compressions are advocated to promote movement of air from the pulmonary artery into smaller vessels where it can be more rapidly eliminated by the lung. Ventilation with 100% oxygen increases the gradient between intravascular air (nitrogen) and alveolar gas to enhance elimination and provides maximally oxygenated blood during a time of reduced perfusion. A central venous catheter or multiorifice atrial catheter may also be aspirated to remove air.¹¹⁸

Postoperative Vision Loss

Postoperative visual loss (POVL) is a rare but devastating complication with multiple etiologies. Its prevalence in spine surgery has been estimated in the range of 0.02%.¹¹⁹ Anterior ischemic optic neuropathy, posterior ischemic optic neuropathy (PION), central retinal artery occlusion, and cortical blindness are all possible causes. An analysis of POVL cases in spine surgery patients revealed PION to be the most common diagnosis.¹²⁰ A recent case-control study identified six independent risk factors for PION after spinal fusion surgery: male gender, obesity, use of the Wilson frame, duration of anesthetic, blood loss, and lower percent colloid administration.¹²¹ Recommendations for perioperative management from this study, as well as a practice advisory from the American Society of Anesthesiologists, include considering specific mention of POVL during patient consent for surgery, continuous monitoring of blood pressure and possibly CVP, use of colloids along with crystalloids, keeping the head at or above heart level and neutrally positioned, and consider staging long surgeries.¹²² No specific recommendations regarding deliberate hypotension or specific transfusion threshold are supported by the currently available evidence.

Monitoring for Neurologic Injury

Intraoperative neurophysiologic monitoring techniques are utilized in spine procedures where neurologic injury can occur. An anesthetic technique to facilitate accurate, reliable, and reproducible conditions for intraoperative monitoring requires understanding of the monitoring techniques, knowledge of the effects of anesthetics on intraoperative monitoring, and communication between anesthesiologists, surgeons, and neurophysiologists. Regardless of the intraoperative monitoring techniques or the anesthetic regimen employed, once baseline neurophysiologic signals have been recorded, significant changes in anesthetic depth during key portions of surgical intervention are avoided to reduce confounding influences on signal integrity at a time when the monitoring modality is most useful.

Commonly used intraoperative monitoring techniques during spinal surgery are somatosensory-evoked potentials (SSEPs), motor-evoked potentials (MEPs), and the intraoperative wake-up test. Somatosensory-evoked potential monitoring is used during spinal surgery to assess for injury at the nerve root or dorsal column level. While not degraded to the same extent as MEPs, SSEPs exhibit a dose-related increase in latency and decrease in amplitude

under volatile anesthesia and volatile agents should be dosed below one MAC (minimum alveolar concentration) to maintain SSEP signal quality. Opiates are often coadministered with volatile agents and do not affect signal quality. Nitrous oxide is typically avoided as it results in further degradation of the signal. The use of intravenous anesthetics such as propofol, thiopental, or midazolam infusion results in superior signal quality compared with volatile agents. Ketamine and etomidate are reported to increase the amplitude of SSEPs, though the effect that this has on their sensitivity and utility remains a matter of speculation. Neuromuscular blocking agents have no effect on SSEPs.¹²³

Of the monitoring techniques described for spinal surgery, MEPs are most sensitive to anesthetics. Preliminary work showed that MEPs were extremely sensitive to anesthetics even at subclinical doses.¹²⁴ Subsequently, use of multipulse stimulation techniques improved both low amplitude baseline signals and anesthetic depressed MEP signals. All anesthetics cause a time-dependent decrease in MEP signal amplitude, proportionate to the length of surgery regardless of the anesthetic regimen referred to as “anesthetic fade.”¹²⁵ Anesthetic fade can be overcome by increasing stimulation energy but this may lead to false-positive signal changes.

All currently used agents cause significant dose-dependent depression of MEP signals. Although MEPs are recordable with desflurane or sevoflurane at 0.5 MAC, there is little evidence to show adequate clinical recording conditions with a volatile anesthetic as compared with total intravenous anesthetic options.^{126,127} Propofol is currently the most popular anesthetic agent for the maintenance of anesthesia during MEP monitoring due to its titrate ability and favorable pharmacokinetic profile. Propofol at clinically relevant concentrations does not significantly affect MEP responses.¹²⁸ Although bolus administration of propofol can lead to loss of MEP signals, signals return within minutes.¹²⁹ Other intravenous anesthetics, including midazolam, ketamine, and etomidate, do not clinically significantly suppress MEPs. At target-controlled plasma concentrations, remifentanyl has the least effect on MEPs, although all opioids produce adequate recording conditions.¹³⁰

Neuromuscular blockade is frequently used to facilitate tracheal intubation and surgical exposure. Boluses of muscle relaxants lead to loss of MEPs, as they block signal transduction at the level of the neuromuscular junction. Careful infusions of neuromuscular blockers with 20–50% maintenance of single twitch height have been shown to

allow reliable MEP recordings when used in conjunction with a minimally suppressant anesthetic and multipulse transcranial electrical MEP.¹³¹ Patients with preoperative neurologic deficits appear to be more sensitive to the depressant effects of neuromuscular blocking drugs.¹³² A short acting neuromuscular blocking agent may be used at the time of induction of anesthesia; however, maintenance of neuromuscular blockade or rebolusing can pose considerable challenges to MEPs interpretation.

Intraoperative Wake-up Test

The wake-up test involves emerging a patient from a general anesthetic during a surgical procedure to allow clinical assessment of the patient's neurologic function (following commands to move hands and feet). The wake-up test is simple to perform and requires no neurophysiologic equipment or staff. It can be used in conjunction with neurophysiologic monitoring such as MEPs to allow for clinical correlation when electrophysiologic changes are detected. For a wake-up test to be clinically practical, a general anesthetic technique that allows for rapid emergence is desirable. Maintenance of anesthesia with either desflurane or propofol along with a remifentanyl infusion can facilitate performing a clinical neurologic examination in as little as 5 minutes.¹³³ Use of remifentanyl in spinal surgery has its limitations as remifentanyl does not provide any postoperative analgesia and may lead to postoperative hyperalgesia. If remifentanyl is chosen as an intraoperative opioid to facilitate a rapid wake-up test, the patient will require other analgesics prior to the completion of surgery for adequate initial postoperative analgesia. Sufentanil or fentanyl may be more clinically appropriate opioids for infusion during spinal surgery, although time to perform a wake-up test will be delayed.

KEY POINTS

- Perioperative optimization of patient comorbidities affects patient and surgical outcomes and requires a multidisciplinary approach to reduce perioperative complications.
- Patients with acute cervical spine injuries are at risk for ventilatory failure requiring intubation. Intubation needs to be undertaken with care to avoid secondary SCI. Patients with SCI should have an MAP maintained at 85–90 mm Hg for the first 7 days following acute SCI.

- Preoperative anemia is common and associated with postoperative mortality. A multidisciplinary blood management program can optimize patients prior to surgery and reduce the requirement for allogeneic transfusion of blood products.
- In these challenging patients, it is imperative to treat perioperative pain resulting from spine surgery aggressively using a multimodal approach to prevent long-term sensitization of the CNS and the development of a chronic pain state.
- Prone positioning during spine surgery is associated with complications including VAE and postoperative vision loss. These complications should be anticipated and steps taken to reduce associated modifiable risk factors.

Male gender, obesity, use of the Wilson frame, duration of anesthetic, blood loss, and lower percent colloid administration have been identified as independent risk factors for postoperative visual loss after spinal fusion surgery. It is recommended to consider specific mention of POVL during patient consent for surgery, continuous monitoring of blood pressure and possibly CVP, use of colloids along with crystalloids, keeping the head at or above heart level and neutrally positioned, and consider staging long surgeries.

Spinal Orthoses

INTRODUCTION

The spine can be divided into five segments based on anatomic and biomechanical considerations, including C1-2, C3-T1, T2-T10, T11-L4, and L5-sacrum. Each of these segments is unique and should be considered differently with respect to orthosis use. However, for organizational purposes, this chapter will be subdivided into cervical and thoracolumbosacral segments.

US Food and Drug Administration (FDA) clearance is not required prior to clinical use of spinal orthoses as the FDA categorizes all spinal orthoses as class I devices. Therefore, spinal orthoses can be manufactured and marketed for public use without rigorous proof of safety or efficacy.¹ Currently, spinal orthosis is prescribed for many different reasons including deformity correction, fracture stabilization, or simply to limit physiological spinal motion associated with degenerative conditions or to provide the patient with proprioceptive feedback.

The principle of preventing motion in the adjacent joints, as used in the extremity, also applies to the spine. However, due to the multisegmental nature of the spine, the junctional levels adjacent to the injured segment must be immobilized. As such, when stabilizing the cervical spine, the head and the thoracic spine must be immobilized and when stabilizing the lumbar spine, the pelvis and the thoracic spine are immobilized. Compared to surgical management of spinal disorders, the use of orthosis may seem benign; however, it is not without risks and

complications. These devices have been associated with skin irritation, muscular atrophy, osteopenia, joint stiffness, mortality, and severe discomfort.²⁻⁸ Orthoses can be particularly troublesome in the obese patients.

CERVICAL ORTHOSIS

The unique anatomy within the upper cervical spine and subaxial spine makes immobilization challenging, and different devices are required depending on the location of the injury. The stabilization of the cervical spine depends on immobilization of the skull, usually via occiput and the mandible proximally and the clavicle and/or thorax distally.¹ Hard contact against the mandible and occiput is associated with skin complication and impairment of mandibular movement can interfere with mastication. Increased rigidity of the device can increase these associated risks. Distal immobilization is challenging because the clavicle moves with shoulder motion and the soft tissues around the shoulder and the upper trunk are variable in size and shape. All of these factors along with the degree of injury must be taken into consideration. The clinician must choose a device that meets the patient-specific needs while minimizing complications.

The primary indication for the use of cervical orthosis is instability. This includes instability caused by trauma, tumor, infection, inflammatory diseases, and iatrogenic instability postsurgery. Orthosis is also used for the treatment of chronic or degenerative disease of the cervical spine, including radiculopathy or myelopathy.

Cervical orthoses are divided into four general categories: the cervical collar, the poster brace, the cervicothoracic orthosis (CTO) brace, and the halo ring-vest fixator (Figs. 14.1 to 14.6). The cervical collar comes in soft and hard varieties and generally extends from the occiput and mandible down to the clavicle. The poster brace and the CTO are similar devices with the CTO extending slightly more distal and incorporating more of the chest usually with a circumferential strap, while the poster brace is best described as a cervical collar with extension down to the chest and/or the back. Cervicothoracic orthoses and poster braces control the head through padded mandibular platforms and supports at the back of the occiput. Rigid up-rights then attach the head to the thorax via thoracic plates and/or straps. The halo fixator is a device that connects the head to the thorax via pins that pierce the outer table of the calvarium and subsequently attach to a vest around the chest via rigid metal ring and bars. More extensive versions of the halo fixator connect the head to the body via plaster of paris body cast or pins in the pelvis.

Cervical Collar

Among of all the options, the soft collar (Fig. 14.1) is the least stabilizing prosthesis,^{9,10} providing no more stability than a

turtle neck sweater.¹¹ However, it is also the least expensive and is associated with little patient discomfort. This device is only indicated to provide proprioceptive feedback to the patient. Neck pain post-trauma may be treated with a soft collar for a short period as long as no potential for instability exists.

The most commonly used cervical orthoses are rigid cervical collars; examples are demonstrated in Figures 14.2 and 14.3. There are also custom-made variations of each, but they will collectively be referred to as cervical collars. These collars tend to be effective in minimizing motion in the sagittal plane and to a lesser degree for lateral bend and axial rotation.¹² Multiple biomechanical studies have compared the effectiveness of these devices. Most commercially available cervical collars appear to be effective in immobilizing the spine, although the custom-made varieties are more comfortable.^{1,8,10-14} These devices are commonly used prophylactically in trauma patients until the cervical spine is safely cleared. It is important that these devices be removed as soon as injury to the cervical spine is ruled out. Beyond the complications of skin irritation, difficulty with ingestion and speaking as well as general discomfort, rigid collars may cause increased intracranial pressure, which can be perilous in patients with traumatic brain injury.²

Cervicothoracic Orthosis

The CTOs such as the Minerva (Fig. 14.4) or SOMI (sternal-occipital-mandibular immobilizer) brace (Fig. 14.5), as well as other custom orthoses, are designed to stabilize the cervical spine by immobilizing the occiput and the chest. Cervicothoracic orthoses have been shown to be more effective than cervical collar and are a good option for immobilization of the cervical spine.^{12,13,15} The Minerva is an effective brace and in some instances has been shown to be more effective than halo immobilization as it does not lead to the snaking phenomenon.¹⁶ Nonetheless, with the introduction of the halo, the use of CTOs has decreased.¹

Halo-vest Device

The halo-vest device is generally accepted as the most effective method of upper cervical spine stabilization, even though the halo allows for substantial motion in the lower cervical spine.¹⁰ Furthermore, the halo can be associated with a snaking phenomenon, whereby neck muscle contraction causes translation of individual vertebrae in the midcervical spine due to immobilization of the

upper and lower segments.¹⁰ The halo device is commonly used to stabilize the cervical spine when the rigid collar and CTOs are deemed to be insufficient. A more recent biomechanical study comparing a rigid collar, a soft collar, and CTO to a halo, found the halo to be the most effective device in stabilizing the spine.¹⁷ However, other studies have found the halo to be less effective than a rigid cervical collar in stabilizing the middle or lower segments of the cervical spine.¹⁰ When using this device, careful consideration must be given to patient selection to avoid complications. Absolute contraindications to the use of the halo include cranial fractures, infections, and severe soft-tissue injury at proposed pin sites. Relative contraindications include chest trauma, obesity, pregnancy, advanced age, and Barrel-shaped chest.³ The elderly population is particularly at high risk of halo-related complications. Many authors have reported a high rate of complications associated with halo use in elderly (>65 years).⁶ The mortality rate of elderly patients treated with halo has been reported to be as high as 40%, with one group reporting a two-fold increase in mortality and major complication rate in elderly patients treated with halo compared to those treated with cervical collar.^{6,7,18} Horn et al. have also reported high

complication rate with halo use in the elderly; however, they concluded that the high complication rate was due to multiple comorbidities seen in this population.⁵ Others have also compared halo fixation to posterior cervical fusion for odontoid fractures in the elderly and concluded that the risk of surgery, although not trivial, is less than the reported risks of halo treatment.¹⁹ Although the majority of these studies are based on small patient populations with limitation in randomization and blinding, the use of a halo in the elderly is a relative contraindication. Also, complication of screw loosening, loose fixation, pin site infection, skin necrosis, and even intracranial penetration from a fall can occur.^{4,20} Another option to the halo is the Lerman noninvasive halo system, which has been shown to be very effective in children.²¹ This noninvasive halo system can provide children with congenital torticollis, C1-C2 rotatory subluxation, and odontoid fractures with immobilization without the risk of pin penetration into the skull.²¹

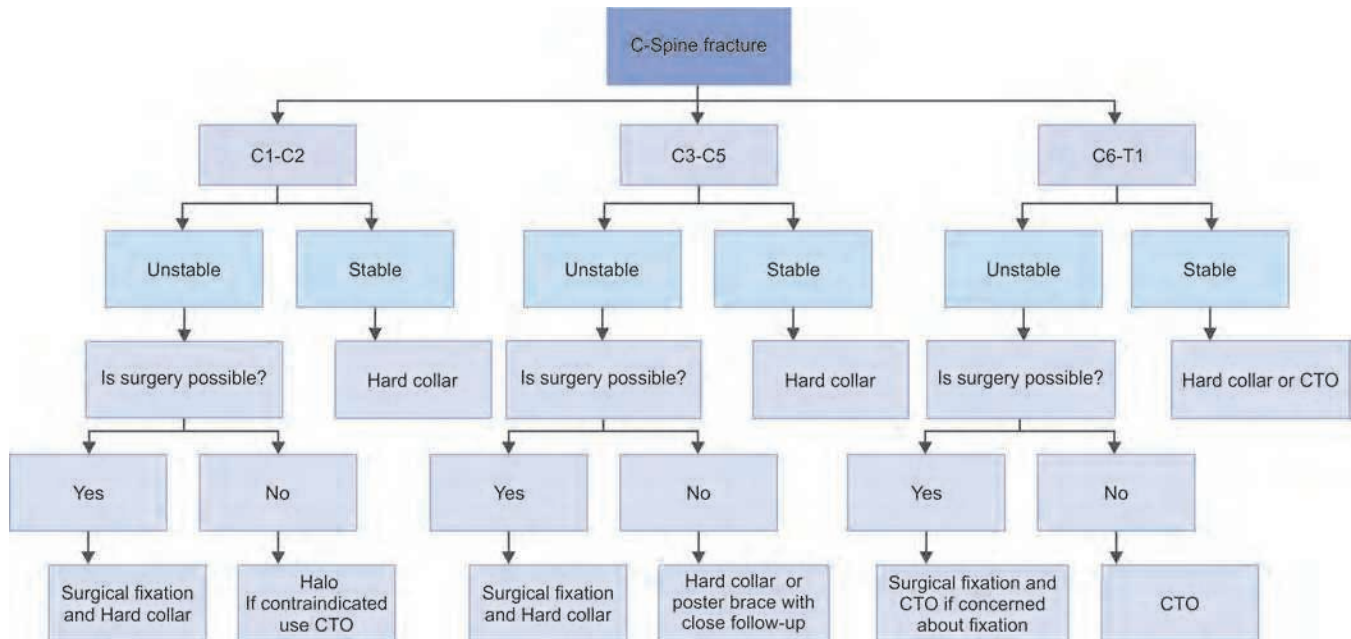

Poster Brace

Multiple varieties of the poster brace have been manufactured in an attempt to better control motion at the cervicothoracic junction. Most of these are modifications to hard cervical collars that extend down to the thorax. Effectively, poster braces junction much like the SOMI or Minerva.

SELECTION OF THE APPROPRIATE ORTHOTIC

In this section, recommendations are made toward the selection of cervical orthotic use in the treatment of common spinal trauma. These recommendations are summarized in Flowchart 14.1. In each scenario, careful follow-up with standing or sitting X-rays in the orthosis is essential. For all fractures, the indications for surgical intervention must be excluded prior to initiating conservative care. Indications for surgical intervention are discussed in detail within other chapters of this textbook.

For fractures of the atlas (C1), determination of fracture stability must be made, which is based on the integrity of the transverse ligament. If the transverse ligament is disrupted, the fracture is considered unstable as significant instability is likely to exist between the first and the second vertebra. Significant displacement of the C1 lateral masses will lead to malalignment of the C0-C1 and/or C1-C2 articulations. For unstable fractures of atlas, surgical management in the form of reduction and instrumentation

Flowchart 14.1: Algorithm for management of cervical spine fracture.

followed by hard collar immobilization for up to 3 months is recommended. However, an alternative to surgical fixation is the use of the halo-vest device. If the halo-vest device is otherwise contraindicated, then a CTO should be considered. If the fracture is stable, treatment with a hard collar for approximately 3 months with routine clinical and radiographic follow-up to confirm fracture union should be undertaken.

There are multiple patterns of axis (C2) fractures; however, the two most common are the odontoid fracture and hangman's fracture. Spinal stability must once again be determined. Generally, displaced fractures at the base of the dens (type II) and hangman's fractures with disruption of the C2-C3 disc space are unstable. As such, surgical fixation should be considered for these fractures.²² Alternative treatment to surgical management is halo-vest stabilization with or without closed reduction. In the elderly, in whom halo-vest stabilization may be contraindicated, we recommend a CTO; however, in some circumstances, patient factors may indicate a simple hard collar for the treatment of type II odontoid fractures. In the case of stable hangman's fractures or dens fractures (example most type I and type III), we recommend the use of a hard collar or CTO with routine follow-up until fracture union.

Injuries of the middle cervical spine including fractures from C3 to C5 are the most difficult to immobilize

with an orthosis as biomechanical studies have shown that the mid-cervical spine is the most difficult part of the cervical spine to control with a brace. If the fracture pattern is stable with no substantial malalignment or cord compromise, use of well fitted hard collar for approximately 3 months is recommended. However, if the fracture pattern is unstable, then surgical management must be considered. Further consideration for the use of a hard collar postoperatively can be made if any doubts exist as to patient reliability, to protect the soft tissues, or immobilize associated injuries. Fractures of the cervical spine below the C5 level should be immobilized with a CTO. For simple injuries such as isolated spinous process fracture or transverse process fracture, a soft collar prosthesis is likely all that is needed. In some cases, a cervical collar can actually increase cervical motion during certain activities such as eating.

■ THORACOLUMBOSACRAL ORTHOSIS

Bracing for Treatment of Deformity

The spinal deformity for which orthoses are most commonly used is scoliosis in attempt to halt progression; however, studies have failed to show that bracing will reverse any existing deformity and the use of bracing to treat scoliosis is viewed as futile by some. Classic indication

for orthotic use in adolescent idiopathic scoliosis is the treatment of skeletally immature patients with curves that measure 30–45°, or the radiological progression of the curve >5° in patient in whom a previously recorded measurement was 25.²³ Treatment of idiopathic scoliosis with orthosis is generally continued until full skeletal maturity unless further progression despite brace use necessitates surgical management. In other forms of scoliosis such as neuromuscular or congenital scoliosis, bracing is ineffective in inhibiting progression; however, it can be used as a temporary measure until surgery is performed or as an alternative treatment when surgery is not possible. Other types of spinal deformity can also be treated with bracing; in particular, Scheuermann's kyphosis can be treated with satisfactory outcome in patients with curves of 50–55.²⁴

Biomechanics of Bracing Spinal Deformity

Braces are used to correct sagittal and coronal deformity by applying corrective external pressure forces at osseous structures that are attached to the vertebral column. The ribs and the sternum are used to apply corrective forces on the dorsal spine; the pelvis is used as a contact point for lumbar spine. Correction of the coronal deformity is done by applying three-point bending forces to the thoracic curve, pressure applied to ribs corresponding to the apex of the deformity, whereas the pelvis and the axilla serve as the opposing contralateral pressure points. For lumbar curve deformities, pressure is applied to the level of the deformity with contralateral pressure applied to pelvis and the thorax. Correction of sagittal deformity is done by applying pressure over the sternum and anterior superior iliac spine anteriorly and the spinous processes posteriorly. The amount of pressure applied can be adjusted by varying the thickness of the pads over the pressure areas. An increase in pad thickness over pressure areas will increase the amount of correction yielded. The magnitude of correction is also controlled by the height of axillary pads, with higher pads leading to greater correction by increasing the moment arm.^{25,26}

Complications of Bracing

The use of brace for the treatment of scoliosis is not completely benign. Most patients find the brace to be very uncomfortable and a significant social inconvenience.

Skin irritation and pigmentation can also occur, especially in hot climate regions. Furthermore, brace use has been associated with significant respiratory impairment in patients with neuromuscular scoliosis.²⁷ Another major issue with brace wear is compliance. As such, proper patient and parents counseling is essential and psychological assessment has been advised as means of improving compliance.²⁸ Many authors have investigated patient compliance with brace treatment: Helfenstein et al.²⁹ used a temperature probe to record the temperature at the skin-brace interface, while Rahman et al.³⁵ used similar methods of measurements and were able to demonstrate a correlation between time spent in brace and success of treatment.²⁹

Types of Orthosis Available for Scoliosis

Milwaukee Brace

The Milwaukee brace is a custom-made cervicothoracolumbar orthosis used in the treatment of scoliosis. The device is a full torso brace, which extends from the skull to sacrum. The Milwaukee brace can be used for curves that extend above T8. This brace utilizes rigid metal bars to connect a thoracolumbar rigid brace to a cervical component; as such, it is generally poorly tolerated and is rarely used at our center.

Charleston Brace and Boston Brace (Figs. 14.7A to D)

The Charleston and the Boston brace are custom-made thoracolumbosacral orthoses, which work by applying three-point bending forces to the thorax and pelvis. These braces are most commonly prescribed at our center and at most other centers in North America. They are effective forms of bracing for curves with apex below T7 and above L2. The Boston brace has been shown as an effective treatment modality for idiopathic scoliosis, perhaps decreasing the need for surgery and in some cases more effective than the Charleston.^{30,31} The Charleston brace is prescribed for nighttime use only and it is too uncomfortable and cumbersome to consider for use during the day. The brace holds the patient in overcorrected position. Despite reduced wear schedule, patient compliance was poor due to the discomfort frequently reported with its use. This can be an excellent option for patients who are not willing to wear the brace during the daytime. The more classic Boston brace is designed to be more cosmetic and comfortable and to be worn during the day as well as nighttime.

Figs. 14.7A to D: Charleston brace in pink and Boston brace in white.

Providence Brace

Providence brace is another brace for dedicated nighttime use. Curve correction occurs through application of lateral and derotational forces. It results in a tilt of the shoulder and truncal rotation, making walking or even standing in the brace very difficult.¹⁵

SpineCor Brace

SpineCor brace is an example of a nonrigid brace, which works on the principle that scoliosis is caused by postural disorganization, muscular dysfunction, and unsynchronized spinal growth. The SpineCor brace consists of thermo-plastic pelvic base, thigh and crotch bands, a cotton bolero,

and four corrective elastic bands of variable sizes. It is worn full time and it is relatively comfortable with a very low profile making it less visible under clothing. The effectiveness of this brace has been demonstrated by Coillard et al. who reported a 95% success rate in their carefully selected patient population.³²

Progressive Action Short Brace

The progressive action short brace (PASB) is a less bulky brace compared to the more traditional Boston type braces, allowing freedom of movement of trunk and wearing clothes beneath. For these reasons, compliance is reported to be higher with satisfactory results.³³ This brace works by a different mechanism than the three-point bending force theory. The biomechanical principle is to constrain spine dynamics and inhibit curve progression by inverting the abnormal load distribution during growth. The biomechanical concept is to apply external forces aimed at producing a partial reduction of the deformity that is followed by a generation of continuous internal corrective forces.

In summary, we advocate the use of spinal orthosis in the treatment of scoliosis. The clinician must take into account patient factors, deformity factors, as well as the experience and abilities of the local orthotist. Generally speaking, for curves above T8, the Milwaukee brace should be considered. For curves below this, the Boston brace, Charleston, Providence, Spinecor, as well as PASB are all potential options.

Fig. 14.8: Jewett brace.

cautioned to not become dependent on bracing as this can result in atrophy of the core muscles and long-term dependence on the brace. Patients should be cautioned to use a lumbar brace intermittently as part of the larger treatment protocol that includes core strengthening and physical therapy.

THORACOLUMBAR TRAUMA

Orthoses are commonly utilized for the nonoperative treatment of many fractures within the thoracolumbar spine. The wedge fracture, burst fracture, and seat-belt injury are appropriate fractures to be treated with a brace. For these fractures, the deforming force to be braced against is within the sagittal plane. The use of a hyperextension type orthosis, such as the Jewett brace (Fig. 14.8), has demonstrated very good outcomes.³⁴ When the fracture is also potentially unstable in the coronal plane, an off-the-shelf or custom-made thoracolumbosacral orthosis should be considered.

DEGENERATIVE CONDITIONS

Spinal orthoses can also be useful in treating painful degenerative lumbar conditions by providing support to the core muscles in the lumbar spine. While lumbar braces can effectively alleviate back pain, patients should be

INTRODUCTION

Shifts in measuring success of treatment and in the doctor-patient relationship over the past 20 years have substantially impacted the manner in which patient outcomes are measured, particularly in surgical fields. Where outcomes were once largely reported in terms of technical success or failure of an operation, the evolving recognition that healthcare is consumer-driven has drastically increased the importance placed on patient satisfaction and recovery of function when measuring elective surgery outcomes.

A second paradigm shift that is less well established at the time of publication of this textbook, but certain to become increasingly important in coming years is the measurement of the success of treatment on a cost basis. The unsustainable pace of increasing healthcare costs in many western countries, particularly the United States, has drawn interest to the use of outcome metrics to measure the relative cost-benefit proposition of different treatments and some healthcare systems have begun to rely on these instruments and the associated analysis to make decisions about rationing healthcare. While such practice is not yet widespread, the mounting pressure on payors leaves little doubt that treatments will need to be justified

on a cost-effectiveness analysis (CEA) basis in the near future. This heavy fiscal influence on the practice of medicine creates an imperative for physicians to develop at least a working understanding of the concepts underlying CEA to ensure that outcome measurement accurately captures the benefit provided to patients by appropriately indicated and provided treatment.

TIME POINTS FOR DATA COLLECTION

The minimum publishable follow-up period for all spinal reconstruction surgery is typically 2 years. It is the author's practice to collect outcome instruments at baseline and then postoperatively at 3 months, 6 months, 1 year, and 2 years. Although some investigations may require even longer follow-up, we typically collect data after 2 years only when needed and do not routinely follow patients without new or persistent complaints in order to reduce the financial and personnel burden associated with data collection. Although some procedures such as microdiscectomy may be reasonably discharged after 1 year of symptom-free follow-up, it is our practice to follow all patients for 2 years and collect outcome instruments at intervals specified above.

DATA SOURCES FOR MEASURING OUTCOMES: PHYSICIANS, PROCESSES, AND PATIENTS

Physician-derived outcome measures were once widespread and have the advantage of being easily and inexpensively collected without the need for patient questionnaires and the associated cost and time. These few advantages are heavily outweighed by the physician bias toward favorable results, reliance on physician subjectivity to identify qualitative outcome categories (i.e. excellent vs. satisfactory), uncertainty as to whether these measures capture outcomes important to patients and the inability to compare outcomes across different diagnoses, a necessary feature for CEA. While western medicine has appropriately moved away from the use of physician-derived outcome measures, these measures are still useful in some databases compiling results when patient-derived outcome measures are not used or not of primary concern such as the American Board of Orthopaedic Surgeons' board collection database.

Process-based outcome measures are recorded at the time of delivery of care and usually quantify some aspect of treatment. Examples relevant to spinal surgery include operative time, intraoperative blood loss, length of hospital stay, whether the patient received preoperative antibiotics, and readmission rate after surgery. These measures are recorded as a part of medical record documentation and accessible from surgical, nursing, anesthesia, billing, or hospital records. Because they can be retrospectively queried and do not require any departure from the typical delivery of care, they are minimally burdensome to collect. Process-based measures are usually objective and may be less biased than some physician-based or patient-based measures and often can be interpreted or analyzed using simple methods. Process measures, however, often do not reflect patient's quality of life and function, qualities that are increasingly important in describing surgical outcomes. Furthermore, process measures can be gamed by physicians and hospitals without significant changes in the quality of care provided. Process-based measurements are used in some instances in the absence of patient-centered outcome measures to determine reimbursement rates such as has been implemented with the Surgical Care Improvement Project (SCIP) measures. To improve care in these areas, the program has identified nine specific process measures that are tracked nationally. While reporting by hospitals is voluntary, Medicare will decrease reimbursements by 2% if a hospital does not report its rates

of compliance. This type of reporting may be used in the future to more strongly influence reimbursement rates. While such use of process measures is likely misguided due to the uncertain impact on patient outcomes, it is likely to continue in the future if payors are not provided with better patient-centric data on which to base decisions and reimbursement, particularly given the ease of collection of process measure data.

The use of patient-derived outcome measures reflects a growing recognition that outcomes in healthcare should describe patient's function and quality of life. Strengths of patient-derived outcome measures include direct insight into how the primary consumer of healthcare perceives his/her outcome and the ability to learn about less tangible factors that are not captured during a brief encounter with a physician and would not be reflected by physician-driven measures but are nonetheless important to patients. There are many challenges in using patient-derived measures that practically limit their use, including the time-consuming nature of many of the questionnaires for patients and the additional infrastructure necessary to distribute, gather, score, and catalog the questionnaires. These tasks usually will fall on the physician and are not reimbursed. Some instruments are proprietary and associated with an additional cost for interpretation. Physicians must have a strong motivation to perform research or to carefully monitor their patient's outcomes to take on the extra workload and cost. Finally, most questionnaires cannot be completed by patients with cognitive limitations and functional components may not accurately represent the outcome for patients with severe physical limitations, patient populations who equally deserve to have outcomes measured and optimized.

PATIENT-DERIVED OUTCOME INSTRUMENTS: GENERAL HEALTH VERSUS DISEASE SPECIFIC

Outcome measures used in spinal surgery may be designed to provide general information about a patient's function and well-being or may be more focused on a specific region of the spine or even a certain spinal condition. Examples of general health instruments are questionnaires such as the Short Form-36 (SF-36) or EuroQol-5D (EQ5D). General health measures are attractive because they allow comparison between patients with different diseases and because some of these instruments can be used in cost-effectiveness calculations by surgeons, researchers, and interested governmental and payor organizations. Downsides include

the lack of specificity to the condition being treated and greater potential for confounding effects by concurrent treatment of nonspinal pathology, which may change scores independent of spinal treatment. Most research on treatment of spinal diseases will use both a general health and disease-specific outcome measure to overcome some of these limitations.

General Health Outcome Measures

The SF-36 is a proprietary instrument developed systematically as a part of the Medical Outcomes Study (MOS), which was first described in 1982.¹ The survey includes 36 questions that the patient answers by selecting from five provided responses, yielding a composite score in eight different health domains grouped into physical or mental domains. It does not, however, provide a single composite score and cannot be graded without entering into a fee-based licensing agreement (*QualityMetric*, Lincoln, RI). Two domains (bodily pain, physical functioning) have been used as independent outcome measures in the spine surgery literature, most prominently in the Spine Patient Outcomes Research Trial (SPORT) studies.²⁻⁴ The SF-36 has been translated into numerous languages and validated many times.⁵⁻¹⁰

Shorter versions of the SF-36 have been developed to reduce the length of time it takes to complete and score the questionnaire, resulting in the SF-12 and SF-6D. Both questionnaires consist of a subset of SF-36 questions demonstrated to most closely predict the SF-36 domain scores based on regression analysis. One limitation of both shorter questionnaires is that they cannot be broken into the same eight health domains that make up the SF-36, but are only broken down into physical and mental subscores. The SF-12 has been validated for use in patients with low back pain¹¹ and cervical myelopathy.¹⁰ Practically speaking, the SF-12 is widely used and there is no pressing need to demonstrate validation in all specific subsets of patients with spinal disease. The SF-6D is used commonly in analyses evaluating value in healthcare,¹²⁻¹⁴ an increasingly important aspect of outcome measurement, as it can be used to derive a utility score, the concept of which is discussed below.

The SF-6D is not the only proprietary instrument that can be used to measure general health and function. The EuroQol Group is a consortium of European researchers who developed a questionnaire designed to measure overall health and function, an instrument that is widely used in studying cost-effectiveness across all types of illnesses.

This instrument, known as the EQ-5D, was initially validated in England, The Netherlands, and Sweden, providing nearly identical results in each study site that led to rapid and widespread adoption in Europe.^{15,16} Although this questionnaire has been validated in the United States population as well, adoption in the United States has been slower, likely due to the availability of the domestically developed SF-6D. The EQ-5D questionnaire is composed of five questions, which were based on surveys about health perceptions completed by lay people and which cover different areas of human well-being—mobility, self-care, activities of daily living, pain, and anxiety/depression. Responses are divided into three states of relative function with the domain in question (no problems, some problems, and extreme problems) allowing for a total of 243 distinct health states. The EQ-5D is proprietary and is commonly used in cost-benefit studies,¹⁷⁻²¹ but requires purchase of a license to use the questionnaire from the EuroQol Group, which is based in Rotterdam, The Netherlands. While some researchers have described similar responsiveness of the EQ-5D and the SF-6D to changes in health state, this is not universally accepted.²²⁻²⁵ In addition to noting that neither questionnaire was validated in a language other than English, a recent review of the use of outcome measures in patients with low back pain suggested that either the EQ-5D or SF-6D questionnaire could be used with no particular advantage or disadvantage of either.²⁶

Disease-specific Outcome Measures

Disease-specific outcome measures focus on topics thought to be important to the spine. In this regard, these instruments may more specifically capture changes in health status related to treatments intended to decrease spine-associated pain or disability while avoiding confounding of outcomes by changes in nonspine health status or non-spine treatments. One major limitation of disease-specific instruments in the setting of increasing importance of CEA is that these instruments cannot be used directly to compare across unrelated diseases, although some spine researchers have tried to develop techniques to convert spine-specific measures into metrics used for CEA as described below in discussions of specific disease-specific outcome measures.

The Oswestry Disability Index (ODI) was developed in England to measure functional limitations associated with low back pain and is easy to use and score.²⁷ The answers for each question are assigned between 0 and

5 or 1 and 6 points depending on the version and simply added to determine the composite score. The composite score is then divided by the maximum possible score (a very useful feature in the case when a patient neglects or chooses not to answer one or more questions)—higher percentages indicate more severe disability. The questionnaire includes questions about functional abilities, activities of daily living, and social life. Since the original questionnaire was first published in 1980, the wording has been modified several times and the ODI has been translated into many languages, although it is not validated in all languages in which it is available. The version currently endorsed by the Musculoskeletal Outcomes Data Evaluation and Management System (MODEMS) initiative and supported by the American Academy of Orthopaedic Surgeons is a modified version containing fewer questions, precluding the use of raw scores instead of the percentage technique described above. The ODI has been widely validated in numerous versions.²⁸ Although there is little evidence that certain versions are substantially more or less valid than other versions, it is important to use only one version within a single multicenter study as subtle variation in scores may occur. Lastly, recent work to develop a method of converting ODI scores to SF-6D scores would increase the usefulness of this outcome measure and allow its incorporation into cost-effectiveness studies,²⁹ although dedicated CEA may benefit from the use of outcome measures intended for this purpose instead of relying on a conversion factor.

The Neck Disability Index (NDI) was developed as a cervical counterpart to the ODI and focuses on cervical spine symptoms and associated limitations. The scale is composed of 10 sections, with five general function sections directly borrowed from the ODI and the remaining five derived by an expert panel who sought to characterize and describe functional limitations related to the cervical spine. Similar to the ODI, each question has six possible answers and scores from each question are simply summed to determine the total score. The NDI has been shown to be reliable and valid^{30,31} and, similar to the ODI, Carreon et al. have developed a methodology to convert NDI responses into SF-6D scores to allow use in cost-effectiveness studies,³² although it has rarely been utilized for this purpose outside of this initial description.

The Zurich Claudication scale is a highly specialized instrument designed not only to apply to a specific part of the spine but also to a particular disease process, lumbar spinal stenosis.³³ This scale measures symptom severity,

functional limitations, and is often used to gauge post-operative satisfaction by focusing specifically on symptoms associated with spinal stenosis such as sciatica and leg strength in relationship to walking. The original description of this outcome instrument acknowledged that it was designed to be used in conjunction with other general health measures to gauge overall function, underscoring one of the weaknesses of such a uniquely specialized outcome measure. There has been no effort to develop a conversion of this scale to a general health measure.

The Japanese Orthopaedic Association (JOA) scale for myelopathy [officially known as the Japanese Orthopaedic Association Cervical Myelopathy Evaluation Questionnaire (JOACMEQ)]³⁴ and subsequently described modified JOA (mJOA) is another spine region and disease-specific instrument. This questionnaire has four sections, which qualifies limitations related to hand function, walking and stair climbing, upper extremity sensation, and micturition. The Benzel modification is the most widely used mJOA scale, which not only translated the questionnaire into English, but also removed culture-specific references from the original version such as descriptions of relative ability to use chopsticks, which would not be relevant for assessment of functional limitations in a western country.³⁵ The mJOA scale is strictly functional as it leaves little room for patients to subjectively assess the magnitude of their disability, instead emphasizing strict objective descriptions of the degree of loss of function.

■ UTILITY MEASURES

The concept of utility measurements is based on the idea that an individual's perception of his/her own health at any time can be represented by a point on a continuous health spectrum along a line from 0 to 1 with a higher score indicating that the individual is healthier. The extremes are defined by 1 = perfect health for 1 year and 0 = death. The utility measure scale is meant to be identical across all diseases meaning that two disease states with the same utility score are equally undesirable, although likely in different ways. Furthermore, utility scores are the ultimate general health instrument as they consider the sum effect of all medical and psychological illnesses that an individual has without any distinction as to the relative contributions of each disease to the overall score.

Direct determination of utility associated with a health state is most often calculated in one of two ways: the standard reference gamble method or the time trade-off method.

The gamble method evaluates a patient's willingness to accept a particular health state and is instructive in explaining how a single scale can be used to compare all health states. This method establishes a probability P at which an individual is indifferent between (1) entering into a gamble where he/she would have either perfect health with the probability P or death with probability $(1 - P)$ and (2) living with the disease state in question. The value of P also represents the utility measure for that disease state. Health states with considerable disability would encourage the individual to accept a lower likelihood of perfect health and a higher chance of death before he/she would become indifferent, leading to a lower utility score for more disabling conditions. While interesting conceptually, the gamble method has obvious limitations in terms of being relatively abstract and impractical as a technique to establish utility scores in a research study setting. Fortunately, as described above, several questionnaire instruments have been designed and validated to yield utility measures with relatively short and efficient questionnaires including the SF-6D and the EQ-5D. These are considered indirect albeit validated techniques to determine utility, which do not use either direct method mentioned above.

The SF-6D is composed of SF-36 questions that evaluate physical functioning, role limitations, social functioning, pain, mental health, and vitality with approximately 18,000 total possible health states based on the five choices for each of six questions. Instead of the two subscores that the SF-36 provides, the SF-6D yields a single utility score that can be used for cost-effectiveness studies. Numerous studies have been performed to compare utility scores derived from the SF-6D and the EQ-5D, the two most commonly used utility score instruments, in many different patient populations³⁶⁻⁴⁰ often leading to suggestions that the two utility questionnaires lead to widely variable utility scores. There is little guidance that one instrument is superior to the other, but these findings raise some concerns about the accuracy of CEA, especially given the often uncertain nature of the cost calculations, which makes up the other important input aside from the utility scores. Within the field of spinal disease, comparisons of utility scores from EQ-5D and SF-6D have similarly identified wide variation in scores, suggesting utility scores calculated from one or the other instrument should not be pooled together in a single study or compared with one another for patients with chronic low back pain⁴¹ or a variety of degenerative lumbar conditions including disc herniation, spinal stenosis, or spondylolisthesis.⁴² Without a gold

standard such as the gamble or time trade-off method performed concurrently, there is no basis for guidance as to whether the SF-6D or EQ-5D has greater accuracy.

UTILITY SCORES FOR SPINAL AND NONSPINAL PATHOLOGY

Reported utility scores for spine patients in cost-effectiveness studies of spinal surgery vary from 0.35 to 0.79,^{14,19-21,43,44} as described above, substantial variation as high as 0.18 was reported depending on which questionnaire (EQ-5D or SF-6D) and version (US vs. UK) was used.²¹ In a study comparing utility between orthopedic patients with a wide variety of problems, the baseline utility of patients with spinal pathology was substantially worse (lower score) than were the utility scores for patients with severe arthritis of the hip, knee, or ankle.⁴⁵ Interestingly, improvement in utility after surgery was greatest for spinal stenosis patients treated with decompression surgery even when in comparison to the improvements shown by patients who underwent total hip and total knee arthroplasty, operations that are widely considered as examples of the most successful surgeries invented in any field of modern medicine. A recent systematic review of the use of cost-utility analysis to study treatment of chronic low back pain described an average preoperative utility of 0.59 across 15 different studies of low back pain, which reported either utility scores or outcome measures that could be converted into utility scores on a post hoc basis.⁴⁶ This provides compelling insight into the difficulties faced by this challenging patient population as recent publications describing utility scores associated with other chronic medical conditions have reported 0.73 for morbid obesity,⁴⁷ 0.7 for type II diabetes,⁴⁸ 0.77 for dialysis patients who perform home peritoneal dialysis,⁴⁹ 0.53 for patients who are treated with traditional hemodialysis,⁴⁹ and 0.64 for moderately severe congestive heart failure.⁵⁰ Spine surgeons should welcome the arrival of CEA-based research due to the great improvement in utility scores associated with well-indicated spine surgery and the low baseline utility scores and associated great potential for improvement in patients with untreated spinal disease.

QUALITY-ASSOCIATED LIFE YEAR

The quality-associated life year (QALY) incorporates the concept of utility and the length of time that a particular health state will last to simultaneously consider quality and quantity of life by multiplying utility and the duration

it lasts. Because perfect health (utility = 1) for 1 year will result in a product of 1 (1.0 utility score \times 1 year = 1), the product of any given utility score and the length of time a health state lasts will give the number of years of perfect health equivalent to living for the utility score in question for that particular length of time. The QALY, therefore, is expressed in units of perfect health for 1 year, allowing comparison across disparate health states with different magnitudes and types of associated disability. From a practical standpoint, QALY calculations typically use average utility measures from indirect outcome instruments such as the EQ-5D or the SF-6D (as opposed to the gamble or time trade-off method) and estimates of the length of time a treatment benefit will last or actuarial data on life expectancy when treatments are expected to change health status permanently.

The QALY data is integrated into cost-effectiveness studies by calculating average change in utility from pre-intervention to final follow-up, which can be attributed to whatever treatment is rendered. The total cost of treatment is divided by the overall change in QALY to provide a cost/QALY that can be compared across different treatments to describe the relative cost-effectiveness of one treatment compared to another. Although it is less intuitive, this number can theoretically be negative due to a negative change in utility—this could either identify a bad treatment that led to a worse health state or may simply describe an effective treatment that slowed the decline in utility in a progressively disabling disease.

Accurate cost calculation is commonly the most difficult and controversial aspect of cost-utility analysis due to lack of cost transparency in many healthcare systems and the complexity of assigning and tracking the indirect costs of treatment. For spine surgery, direct costs include the cost of any instrumentation used, operating room time, surgeon, and anesthesia fees, costs of subsequent hospitalization, imaging, and rehabilitation as well as the cost of complications or treatment failures such as revision surgery. Indirect costs are more difficult to accurately capture and include decreases in productivity/work associated with postoperative recovery and lost productivity of family members who must care for the patient. Additionally, because patients with severe spinal pathology treated nonoperatively often accrue significant costs associated with narcotic analgesics and missing work, avoidance of such expenses may be important to include if surgery results in substantial cost savings. Dividing the cost of surgical intervention including both direct and

indirect costs by the total lifetime QALY gained through the surgery provides a measure of cost per year of perfect health gained and is the basis for comparative analysis between different treatments.

Many cost researchers have adopted the method described above to report QALYs because it is straightforward and there is an intuitive interpretation of the metric. Some authors, however, have objected to the process of multiplying a utility measure and time period to obtain a meaningful quantity. Indeed, this multiplicative model may not match with empiric data in all cases and there are many scenarios in which this measure of cost utility cannot be applied.^{51,52} For instance, QALY is difficult to apply to acute conditions where treatment will lessen pain but ultimately not change the otherwise expected outcome—for example, epidural anesthesia during childbirth compared to natural childbirth cannot be accurately assessed because pain during childbirth is not a persistent state for which a representative utility could be assigned nor could questionnaires realistically be completed during the short window when patients occupy this “health state.” Aggregating utility measures for the purposes of determining “average” improvements in utility associated with treatment also have theoretic disadvantages for decision-making. Strict evaluation of treatment by average QALY, for example, would favor treatment using a therapy which kills half of the patients but restores half to perfect health compared to a second, identical-cost treatment which kept both patients alive but at a utility score of 0.49. This QALY preference is unlikely to be reflected by preferences of individual patients requiring treatment.⁵² Hence, an underlying criticism of QALY is that it is not individualized enough to weigh the health and time preferences and risk appetite of the individual who will undergo treatment.⁵³ Alternate methods to quantify treatment value have been proposed whose proponents claim to overcome these limitations such as healthy-year equivalent (HYE), but have not gained traction or widespread adoption in spinal surgery cost-effectiveness studies. The HYE uses a two-step interview process similar to the gamble method described above with separate scenarios to gauge quality and time considerations to determine utility.⁵⁴ Such research methodology would require substantial financial and personnel resources. In contrast, the QALY can be derived from the SF-6D and the EQ-5D, widely known and well-accepted self-administered instruments. As described above, efforts to derive utility scores from disease-specific outcome measures have been undertaken by Carreon et al. to provide techniques so

that the NDI³² and ODI²⁹ can be used for CEA, potentially encouraging more researchers to engage in cost-effectiveness research using a QALY approach. Until an alternative is developed that is simple and quick to administer, the QALY will likely remain the standard metric for cost-effectiveness studies in spinal surgery despite the limitations outlined above.

The preceding description of CEA highlights the increasing importance of cost in the measurement of outcomes after spinal surgery. While the denominator of the cost/QALY ratio may be favorable for some aspects of spinal surgery due to the related baseline disability and successful nature of well-indicated surgical intervention, spine surgery remains very expensive due largely to the high cost of spinal implants. As cost and measurement of outcomes become inseparable and potentially linked to reimbursement, spine surgeons will face greater pressures to help control implant costs, potentially through hospital commitments to a single manufacturer or through judicious use of less expensive implants. A second consequence of the high cost of spinal implants is that the cost structure associated with spinal surgery is heavily front-loaded. Treatments with front-loaded cost structures have a disadvantage in demonstrating cost effectiveness as improvement in utility becomes greater with longer follow-up because the upfront cost is spread over a greater time period. High rates of patient follow-up at such long time points is difficult to achieve.

KEY POINTS

- Reflecting a trend in the practice of medicine in general, spine surgery is moving rapidly toward patient-centered outcome measures and away from surgeon-reported outcome measures.
- The collection of process measures is simple to do and often does not require a major data collection effort, but may not accurately reflect the quality of care delivered.
- General health outcome instruments have the advantage of being comparable across different disease states, but may be less responsive to treatment of spinal disease, while disease-specific outcome instruments should be more responsive to treatment of spinal disease, but are less useful for comparisons between patients with different diseases, an important component when performing CEA.
- A utility score is a number between 0 and 1, which captures the overall health status of a patient; changes

in utility scores are used in CEA to identify the cost of an intervention relative to the change in utility associated with that treatment.

- Cost-effective analysis will become increasingly important to allocate healthcare spending if the cost of healthcare continues to escalate. Longer follow-up is important for cost-effectiveness research in spine surgery because of the high upfront costs and durable benefit to the patient.

HISTORY

A thorough history and physical examination is the cornerstone of diagnosis in the patient with low back pain. Without a thorough clinical evaluation, it is difficult to interpret an anatomic study. Furthermore, the history and physical examination is essential for the development of a treatment plan.

History should include location of back pain, leg pain, and paresthesia, as well as, character, severity, timing (onset, duration, frequency), alleviating and aggravating factors. Pain that is worsened by standing and walking may indicate central spinal stenosis, while pain that is worse with sitting is more consistent with discogenic pain. Progressive weakness or bowel or bladder incontinence may lead to urgent surgical intervention. Previous treatment and medication strategies as well as whether or not they were successful must be investigated in order to determine future treatment options.

Previous history of malignancy, age over 50, ongoing pain of more than 1 month duration, failure to progress with conservative therapy, high sedimentation rate and anemia may raise questions of underlying cancer.¹ History of infection and rheumatologic disease should be noted. Psychological evaluation is also useful in determining prognosis. Factors such as poor job satisfaction, depression, catastrophic thinking, and excessive downtime may predispose to disability.²

Physical examination of the lumbar spine should include inspection, palpation, range of motion, motor, sensory, and reflex examination, provocative maneuvers, and observation of ambulation. Evaluation begins when the practitioner meets the patient. Observation of sitting posture, transfer from a seated to a standing position, as well as gait stability are important. Gait deviations such as steppage gait or compensated Trendelenburg gait may point toward specific areas of weakness or structural deviation of the hip or ankle.

In the anterior plane, asymmetry in shoulder, iliac crest, greater trochanter, and patellar height should be assessed. In the posterior plane, scapular symmetry, scoliosis, posterior superior iliac spine, gluteal folds, popliteal creases, and medial malleolus should be assessed. In the lateral plane, a loss of lordosis or hyperlordosis should be assessed. An increased lumbar lordosis may be a sign of a spondylolisthesis. A loss of lumbar lordosis may indicate acute low back pain with associated muscle spasm. Skin lesions, erythema, ecchymosis, previous surgical sites, or muscle atrophy should be noted.

Palpation of the spinous and transverse processes, iliac crest, greater trochanters, and sciatic notch should be assessed in both the standing and prone positions. Tender points and taut bands can be noted in the lumbar paraspinals, piriformis, gluteals, and tensor fascia lata.

Leg length discrepancy should be evaluated by measuring from the anterior superior iliac spine and umbilicus to the medial malleoli. Motion of the lumbar spine should

Figs. 16.1A and B: Axial and sagittal image of a patient without any pain in spite of a large left-sided intervertebral disc herniation at L5-S1.

be assessed in flexion, extension, side bending, and rotation. Hip and knee range of motion as well as flexibility of the hamstrings, tensor fascia lata, and gastrocnemius mechanism should be evaluated.

The straight leg raise is performed with the patient in the supine position. The examiner passively raises the patient's leg with knee in extension. Pain produced in the posterior leg below the knee between 30° and 70° indicates a positive test, compatible with radicular pain. Crossed straight leg raise results in discomfort in the painful extremity by elevating the contralateral extremity. The slump test is performed when the seated patient flexes his/her chin to the chest. The examiner passively extends the patient's knee and dorsiflexes the foot. In the patient with a radiculopathy, pain radiates down the affected extremity. Femoral nerve test, also known as reverse straight leg raise, causes pain by stretching the femoral nerve in a patient with an upper disc herniation. With the patient in a prone position, the examiner flexes the knee to 90° and then extends the hip, which results in pain radiation into the anterior thigh.

Radiologic evaluation should be interpreted in the context of the clinical picture. Approximately, 30% of patients have discogenic changes in the absence of clinical complaints; this percentage increases with age.³ Conversely, patients may have changes that are impressive to view, but not correlate with clinical presentation (Figs. 16.1A and B).

Conventional X-rays are widely available, easy to obtain, inexpensive, and may provide a good initial screening tool. X-rays can provide information regarding spinal alignment (spondylolisthesis), degenerative changes (disc space

narrowing, osteophytes, and endplate sclerosis), fractures (pars fracture or spondylolysis), vertebral fractures, and cortical bone destruction (neoplastic or inflammatory process). They do not need to be performed routinely and their main utility is an initial evaluation for fracture, malignancy, infection, and instability.

Magnetic resonance imaging (MRI) has superior contrast resolution, which allows for better visualization of soft tissue, nerve roots, disks, vertebrae, spinal cord, and cerebrospinal fluid. It is the best study for looking at the intervertebral disk. It should be ordered with progressive neurologic deficit, unclear diagnosis, concern over malignancy or fracture, and if interventions such as spinal injections or surgery are being contemplated. Magnetic resonance imaging with contrast (gadolinium) allows for better detection of inflammatory processes, tumors, or delineation of recurrent intervertebral disc herniation versus scar tissue in patients who have previously undergone spinal surgery. Disadvantages to MRI are cost, claustrophobia, and contraindications to obtaining an MRI such as pacemakers or other metal implants.

Computed tomography (CT) provides high resolution detail of bony architecture. Computed tomography better evaluates fractures, facet joints, central or foraminal stenosis, and osseous tumors. It is less expensive than MRI and may be used in patients who have contraindications to MRI. It is less sensitive than MRI in detecting infection, tumor, disc herniations, or spinal cord pathology.

Myelography and postmyelography CT is utilized in patients who have contraindications to obtaining an MRI if further evaluation of the intervertebral disc and

neurologic elements is warranted. Patients who have had instrumentation that interferes with the MRI might also require myelography if a surgical procedure for radicular symptoms is being contemplated.

■ DIFFERENTIAL DIAGNOSIS

Axial pain differential diagnosis includes osseous pathology, myofascial pain, facet and sacroiliac joint dysfunction, discogenic and visceral pain. Radiating pain differential diagnosis includes radiculopathy, sacroiliac joint, facet joint pain, and peripheral nerve lesions. Pelvic and long bone fractures, as well as hip and knee joint pathology can also be responsible for lower extremity pain.

Another organizational option is to place patients with low back pain into one of three categories: nonspecific low back pain, back pain potentially associated with radiculopathy or spinal stenosis, or back pain associated with another specific spinal cause (malignancy, fracture, infection, etc.). This is less specific, but may be a more practical initial approach for the patient with lumbar pain. More specific evaluation for the pain generator may take place depending on the individual's progress.⁴

■ TREATMENT

Lifestyle

Obesity is associated but not causative of lower back pain. Patients with chronic spinal disorders are at higher risk for obesity secondary to inactivity, depression, and utilization of medication, which may lead to weight gain. Morbidity associated with obesity includes cardiovascular disease, gallbladder disease, and breast cancer. Obesity results in less optimal outcomes with nonoperative management of degenerative spondylolisthesis and intervertebral disc herniations.^{5,6}

Tobacco has a weak association with lower back pain. Vasoconstriction of vasculature, ischemia, and coughing may result in increased lower back pain related to smoking. There is also an increased risk of nonunion with lumbar fusion secondary to nicotine exposure.⁵

Medication

Nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, muscle relaxants, opioids, antidepressants, and antiseizure medication have been utilized in the treatment of spinal conditions. Medications should be utilized based on

their risk-benefit ratio. Medication that does not provide benefit after a reasonable trial should be discontinued.

Acetaminophen and NSAIDs are usually first-line treatments for spinal pain. They are usually classified together despite the fact that acetaminophen has little, if any, anti-inflammatory effect. These agents are inexpensive and have a well-known adverse reaction profile.⁷ Chou et al. attribute moderate short-term benefits to these agents.⁸

Nonsteroidal anti-inflammatory drugs work by the inhibition of prostaglandin synthesis at the cyclooxygenase receptors. Nonselective NSAIDs block both COX-1 and COX-2 receptors and have both analgesic and anti-inflammatory effects. Known adverse reactions to NSAIDs include potential renal, cardiovascular, and gastrointestinal bleeding. COX-2 selective NSAIDs such as celecoxib are equally effective to other NSAIDs regarding pain relief with less gastrointestinal toxicity and platelet effect.

Corticosteroids have been used to treat spinal pain with limited benefit. There has been anecdotal efficacy in radicular symptoms, first documented in 1970.⁹ Conversely, there have been no randomized clinical trials that prove efficacy of oral corticosteroids in either axial or radicular pain.¹⁰

Opioid analgesics are commonly prescribed for severe acute and chronic spinal pain. They may be considered a second-tier treatment for pain that is not controlled by NSAIDs, acetaminophen, or other nonpharmacologic means. The use of opioids has increased dramatically in the treatment of nonmalignant pain. Unfortunately, the increased volume of opioid prescriptions has corresponded to simultaneous problems of misuse, addiction, and illegal drug diversion. Adverse effects of opioids include somnolence, nausea, vomiting, constipation, respiratory suppression, and addiction. The risk of addiction has been estimated at <5%.¹¹⁻¹⁵

Tramadol is a weak synthetic opioid that also prevents reuptake of serotonin and norepinephrine as its mechanism of action. Because it is a weak opioid, there is less potential for addiction than traditional opioids. Common adverse effects with tramadol include nausea, vomiting, somnolence, headaches, and constipation. Tramadol, when combined with antidepressants with selective serotonin reuptake inhibitor (SSRI) or selective norepinephrine reuptake inhibitor (SNRI) mechanisms, lowers the seizure threshold.

Tricyclic antidepressants have been prescribed in chronic pain patients with depression and these patients had improvement in their pain symptoms. The dosages prescribed for analgesia are less than those used in treat-

ment of depression. Three classes of antidepressants are generally used to treat pain. They are tricyclic antidepressants, SSRIs, and SNRIs. The older tricyclic agents can be very effective for pain and sleep, but are notorious for side effects such as sedation, cardiac arrhythmia, constipation, urinary retention, dry mouth, and weight gain. Selective norepinephrine reuptake inhibitor, the newest class of antidepressants used in treatment of pain, includes duloxetine, which has been approved for treatment of chronic musculoskeletal pain.

Anticonvulsant medications such as gabapentin and pregabalin have been commonly prescribed for neuropathic pain in patients with radiculopathy. The general mechanism of these agents involves inhibition of calcium and sodium channels to decrease glutamate and increase gaba aminobutyric acid (GABA) in the central nervous system. Analgesia occurs by the stabilization of neural membranes. Side effects include dizziness, somnolence, fatigue, headache, swelling, nausea, weight gain, possible rebound seizures, and suicidal ideation.

Other medications that are used for spinal pain and/or radiculopathy include topical agents such as NSAID patches (diclofenac) or topical anesthetics (lidocaine). Counterirritant topical agents such as capsaicin may provide local relief. Antispasmodics such as baclofen, tizanidine, or medication for muscle “spasm” such as metaxalone may be used for axial lumbar pain.

Rehabilitation

The rehabilitation of patients with spinal pain requires a good understanding of the anatomy, biomechanics, and function of the axial skeleton. Although many cases of spinal pain are self-limiting, proper rehabilitation is necessary to reduce the high incidence of recurrence and to facilitate an independent return to preinjury activities and prevent future disability. A successful rehabilitation program is multifaceted and focuses on correcting an individual's biomechanical abnormalities with the use of a structured exercise program. Education on posture and proper body mechanics will also help prevent further injury and pain. It is important to note that the goal of a rehabilitation program for patients with chronic spinal pain is to maximize function and facilitate independent management of the condition even with an ongoing impairment. Due to the complexities of the biopsychosocial model of spinal pain,¹⁶ an interdisciplinary approach may be the best way to prevent long-term disability in patients with certain risk factors.

Stability of the spine is achieved both passively and

actively. The intervertebral disk, zygapophyseal joints (z-joints), ligaments, and muscles contribute to spinal segmental stability. There are numerous muscles in the spine that act to provide dynamic stability and generate motion. In general, the shorter spinal muscles act as segmental stabilizers, while the longer muscles act as prime movers. Proper biomechanics and function of the spine is dependent on a balance between anterior and posterior muscle activity. Alterations in this balance can lead to abnormal postures and excessive force on various structures in the spine.

In the lumbar spine, prolonged sitting and/or repetitive bending and lifting can lead to abnormal lumbopelvic mechanics and posture. Prolonged sitting with coexposure to whole body vibration and/or awkward postures has been shown to increase the risk of low back pain four-fold.¹⁷ Most postural changes occur gradually over time, allowing for tissues to accommodate without symptom manifestation.

It is usually after a traumatic event (i.e. whiplash or lifting injury) that symptoms arise. In the acute phase, relative rest and protecting the injured tissues will help in pain management. Controlling inflammation and early mobilization of the spine can help prevent atrophy of the spinal muscles and prepare the patient for a therapeutic exercise program. In a comprehensive rehabilitation program, normal trunk and lower extremity strength, endurance, and power should be combined with education and training for posture, body mechanics, and proprioception to allow successful and sustained return to activity.

In acute back pain, the goal of exercise is to manage pain by initiating tolerable movement. In patients with radicular pain, centralization of symptoms is desired. However, numerous randomized, prospective studies and review papers have failed to demonstrate the benefit of exercise in acute low back pain.^{18,19} When direction of movement is selected based on symptoms, more positive results can be demonstrated from an exercise intervention.^{20,21} In patients with posterior disc herniations, extension exercises may be effective in changing intradiscal pressure,²² allowing anterior migration of the nucleus pulposus²³ and decreasing tension on the nerve root. Flexion-based exercises may be more effective in treating zygapophyseal joint pain and spinal stenosis in the lumbar spine by decreasing compressive joint forces.

As the acute pain subsides, the goal is to progress to spinal stabilization or “core strengthening” exercises in order to improve function and decrease the chance of future recurrence of pain. In the lumbar spine, the develop-

ment of a muscular corset, including the rectus abdominus, multifidi, and various pelvic and trunk muscles that attach to the thoracolumbar fascia, can decrease shearing forces across the three-joint complex. Once proper muscle lengthening has occurred, it is possible to strengthen the inhibited muscles via neuromuscular reeducation and closed kinetic chain exercises.²⁴ Initial core strengthening exercises are usually done in the neutral spine position with the pelvis at the midpoint of anterior and posterior tilt, the scapulae midway between protraction and retraction, and the head in the same coronal plane as the shoulders. This decreases tension on the ligaments and joints of the spine and is usually the position of greatest comfort. The next step is to strengthen the prime movers of the spine as well as the extremities while keeping the neutral spine position, which will facilitate neuromuscular coordination. Advancement to dynamic multiplanar strengthening exercises will help in preparation for return to normal functional activities.

A majority of the literature on exercise therapy in treating spinal pain has looked at patients with “nonspecific” low back pain. The ambiguity of this term is evident and serves as one of the major potential limitations in this large group of research articles and review papers. In addition, therapeutic exercise programs come in many forms and are often coupled with multiple cointerventions. Because of the heterogeneity of both exercise treatment options and patient populations, the level of evidence is low. A 2005 Cochrane review of exercise therapy for treatment of nonspecific low back pain concluded that exercise therapy appears to be slightly effective at preventing recurrences, decreasing pain, and improving function in adults with chronic low back pain, but that it is as effective as either no treatment or other conservative treatments in patients with acute low back pain.²⁵ In a more recent review article on nonsurgical care of chronic low back pain, Standaert et al. found low-level evidence that structured exercise improved pain and function within 8 weeks of care, but that it was no more effective than spinal manipulative therapy (SMT).²⁶ Since that review article, a randomized controlled trial with long-term follow-up showed the added benefit of an exercise program with ergonomics training and back school compared to passive therapy in nurses with chronic low back pain (Fig. 16.2).²⁷

Prolotherapy is the injection of an irritant (proliferant) solution into ligaments and tendons for treatment of chronic musculoskeletal pain. Its mechanism of action is the reduction of joint instability through the strengthening of stretched or torn ligaments. This is thought to occur

Fig. 16.2: Proper ergonomic positioning for seating at a desk.

through the release of granulocytes, macrophages, fibroblasts, and growth factors, leading to collagen deposition, thereby strengthening ligaments.²⁸ This may reduce pain and improve overall flexibility and function.

Proliferant solutions are classified into three groups: irritants, chemotactics, and osmotics. Irritants include phenol, guaiacol, tannic acid, and pumice flour. The only chemotactic solution is sodium morrhuate. Osmotics include concentrated solutions of glucose, glycerin, and zinc sulfate.²⁸ A local anesthetic is often added to reduce postinjection pain. Hyperosmolar dextrose appears to be the most commonly used agent today, with sodium morrhuate used slightly less often. Prolotherapy alone has not been proven to be beneficial in the treatment of lower back pain.

However, in the presence of cointerventions, prolotherapy may be more beneficial than control injections alone.²⁹

Traditional Chinese acupuncture is based on ancient beliefs regarding the flow of vital energy, known as *qi*, through the body along pathways termed meridians. Blockage of *qi* is thought to be manifested as tenderness on palpation. Specific points along these meridians are penetrated using fine solid metallic needles to balance the energy flows within the body. Although many different styles of acupuncture have developed over time as its use has spread into other cultures, the traditional Chinese approach appears to be the most widely practiced in the United States.³⁰ Acupuncture has been shown to induce the release of endogenous opioids in brainstem, subcortical, and limbic structures. Functional MRI and positron emission tomography have shown that acupuncture stimulates regions of the brain involved in pain processing, as well as increases opioid binding potential in these same regions. Acupuncture also has effects on local tissues, including mechanical stimulation of connective tissue, release of adenosine at the site of needle stimulation, and increases in local blood flow.³⁰ Adverse side effects, while rare, may include needle site pain, bleeding, nausea, vomiting, dizziness, and fainting.

Several clinical studies have evaluated the effectiveness of acupuncture for chronic lower back pain (LBP). In a recent meta-analysis of 6,359 patients, Yuan et al. concluded that there is no significant difference between acupuncture and sham acupuncture (superficial needle insertion at nonacupoints), for short-term and intermediate pain relief and functional improvement.³¹ However, based on their analysis, they did advocate the use of acupuncture for chronic LBP. Recently, the North American Spine Society has also concluded that acupuncture provides better short-term pain relief and functional improvement than no treatment and that the addition of acupuncture to other treatments provides a greater benefit than other treatments alone.³¹

Spinal manipulative therapy is a frequently applied treatment for back and neck pain. It includes a range of manual therapy techniques applied to the spine; however, the most common usage relates to high velocity low amplitude procedures. Here the practitioner applies a rapid thrust, producing joint cavitation that is often accompanied by an audible “pop.” Articulations in the lumbar spine that are amenable to SMT include the zygapophyseal, lumbosacral, and sacroiliac joints. The effects of spinal manipulation have been shown to include temporary relief of musculoskeletal pain, shortened time to recover from acute back pain, temporary increase in passive range of

Fig. 16.3: Patient in position to receive osteopathic manipulation for the lumbar spine.

motion, physiological effects on the central nervous system, and altered sensorimotor integration (Fig. 16.3).³²

While numerous studies have been conducted on the efficacy of SMT, there is limited evidence advocating its use in chronic LBP. In a 2011 Cochrane review of 26 randomized controlled trials, Rubinstein et al. concluded that there is no clinically relevant difference between SMT and other conventional interventions for reducing chronic lower back pain.³³ A meta-analysis by Shekelle et al. found moderate evidence that SMT has an effect similar to an efficacious prescription of NSAID.³⁴ In contrast, in cases of acute LBP, results from most studies suggest that SMT administered over 2–4 weeks achieves equivalent or superior improvement in pain and function when compared with other commonly used interventions.³⁵

Injection Options for Low Back Pain

Spinal injections for low back pain are utilized for diagnostic as well as therapeutic reasons. Injection options include interlaminar and transforaminal epidural steroid injections, lumbar zygapophyseal (z-Joint) procedures, and sacroiliac procedures. Spinal injections are generally performed with fluoroscopic guidance, although some can be performed with CT guidance. Image-guided approaches have demonstrated increased safety, efficacy, and reliability.³⁶

Contraindications to lumbar spinal injections include active infection, either locally or systemically, bleeding disorders, anticoagulation, uncontrolled hypertension, hyperglycemia, and injectate allergy.

Fig. 16.4: Anteroposterior view of interlaminar epidural steroid injection at L3-L4 on right.

Fig. 16.5: Transforaminal injection at the right L4-L5 interspace.

Fig. 16.6: Left-sided z-joint injection.

Lumbar radiculitis and radiculopathy are the primary indications for epidural steroid injections. Epidural steroid injections have been found to be beneficial for the treatment of acute radiculopathies, especially for short-term outcomes in pain and function.³⁷⁻³⁹ Patients with a lesser degree of nerve root compression, who may have more of an inflammatory etiology for their pain, may respond better to transforaminal steroid injections than patients who have a higher degree of neurologic compression of the nerve root.⁴⁰ These injections may be beneficial in the relief of primarily disc mediated low back pain as well. There are two common approaches to lumbar epidural steroid injections. Interlaminar injections involve the placement of a Tuohy needle, using a loss-of-resistance technique, into the epidural space (Fig. 16.4). A transforaminal epidural injection involves placing the spinal needle

adjacent to the exiting nerve root as it leaves the spinal column (Fig. 16.5).⁴¹ The injectate is usually a combination of a long-acting steroid preparation with a local anesthetic. However, there is little evidence to suggest the addition of a local anesthetic in epidural steroid injections provides improved outcomes.⁴² Potential complications include bleeding, epidural hematoma, infection, epidural abscess, nerve injury, muscle weakness, increased pain, arachnoiditis, paralysis, meningitis, osteomyelitis, spinal headache, and avascular necrosis.³⁸

Adverse side effects of the steroid preparations include skin hypopigmentation, subcutaneous fat necrosis, skin flushing, hyperglycemia, insomnia, hiccups, and fluid retention. Repeated injections can lead to adrenal suppression and cushingoid appearance.

Selective nerve root injections are diagnostic procedures using a local anesthetic to block a spinal nerve suspected of causing associated lumbar radiculitis symptoms. The patient's response to the injection is followed and documented to determine the primary pain generator.

Lumbar z-joint and medial branch nerve block injections are used in diagnosing and treating facet-mediated pain. Symptomatic facet joints have a prevalence of 10-40% in chronic low back pain.^{43,44} Intra-articular injections consist of placing the needle within the joint and injecting the facet joint under fluoroscopic guidance. The medial branch block is done by injecting along the medial branch of the posterior primary ramus as it crosses over the posterior aspect of the transverse process. Pain alleviation from local anesthetic blockade of the medial branch block on two occasions confirms the z-joint as the pain generator. Radiofrequency ablation of the medial branches may provide long-term pain relief (Fig. 16.6).⁴⁵⁻⁴⁷

Fig. 16.7: Intra-articular injection of the left sacroiliac joint.

Sacroiliac joint pain has a reported prevalence of 10–25% of cases of axial low back pain. Sacroiliac joint injections with fluoroscopic guidance are the gold standard in diagnosis and treatment of sacroiliac joint-mediated pain. Steroid containing injections and radiofrequency denervation techniques can be used to provide long-term improvement. Complications include joint rupture and sciatic nerve injury (Fig. 16.7).⁴⁸

KEY POINTS

- Diagnostic studies need to be evaluated in light of the history and physical examination to arrive at a diagnosis and create a treatment plan.
- Medical conditions such as metastatic cancer, infection, and rheumatologic disease should be noted.
- Previous history of malignancy, age over 65, nocturnal pain, and significant weight loss may raise questions of underlying malignancy.
- The use of exercise to treat subacute and chronic lumbar pain is an essential part of treatment, although the evidence is not yet robust.
- Evidence supports that interlaminar and transforaminal epidural steroid injections provide short-term relief of radicular pain.

INTRODUCTION

One of the least understood disciplines in embryology is the development and the pathogenesis of congenital spinal abnormalities. The spine's development into multiple, highly specialized subunits is very sophisticated and not completely understood. Recent advances in genetic laboratory techniques have greatly contributed to our understanding of cell signaling, gene silencing, gene expression, and the pathological disorders.

EMBRYOLOGIC ORIGIN

The process in which a bilaminar disc becomes a trilaminar disc marks the earliest development of the spine, a process called gastrulation.¹ By week 3, the notochord and somites form through molecular signaling from the ectoderm of the trilaminar disk.² Each somite further differentiates regionally; a process called metamerism and ultimately differentiate either into myotomes to become spinal musculature, or into dermatomes to form skin.

An infolding of mesoderm is thought to be formed by the presence of regionally specific cell signaling factors, creating the neural groove. The neural tube will ultimately form from this groove, which is the precursor to the spinal cord. The peripheral nervous system will begin to develop from neural crest cells during neurulation.³

Precartilaginous Stage

At approximately week 4, the mesenchymal cells will divide into three regions: surrounding the notochord, neural tube, and within the body wall. Also at this time, paraxial mesoderm begins to form the precursor of the vertebral column, of bone and disk, the dermis, striated muscle, and connective tissue.⁴

Cartilaginous Stage

At approximately week 6, after cell migration and vertebral body fusion begins, chondrification centers begin to develop within each vertebrae.² Two of these centers in the centrum will fuse to form a large segment of cartilage. Ultimately, sclerotomal proliferation and then differentiation will surround this cartilage to form the annulus fibrosis. Central disintegration of the cartilaginous centrum will then contribute to the nucleus pulposus.² The annulus of the disc starts off as dense cellular regions surrounding the notochord alternating with vertebral bodies.

Segmentation is known as the division of the paraxial presomitic mesoderm (PSM) into somites. These somites are arranged symmetrically in pairs alongside the neural tube and will later form the sclerotome, dermatome, and myotome. Segmentation occurs shortly after gastrulation (20–35 days after conception). Each somite block is affected by different signals in the dorsoventral axis of the

Figs. 17.1A and B: (A) Division of the paraxial presomitic mesoderm (PSM) into somites, (B) the formation of the vertebral body.

embryo. Dorsal somites differentiate into dermatomes by NT-3 signaling from the neural tube, middle somites into myotomes by Wnt7a signaling, and ventral somites differentiate into sclerotomes by Sonic Hedgehog Gene (SHH) signaling from the notochord and floor plate (Fig. 17.1A).⁵

This process continues until a preprogrammed number of somite blocks are formed (33 blocks in humans).⁶ The genetics and pathological disorders resulting from aberrant segmentation will be discussed next.

Molecular Mechanism in the Development of Spine

Cells of the sclerotome, expressing Pax1 and Pax9, begin to migrate toward and around the notochord and neural tube. Once the sclerotomes have surrounded the notochord and neural tube, each level will separate into a cranial area of loosely packed cells (loosed zone; LZ) and a caudal area of densely packed cells (condensed zone; CZ) (Fig. 17.1B). The intervertebral disc will form between these two layers of cells. Some cells in the CZ migrate cranially and differentiate into the annulus fibrosis by expressing transforming growth factor beta, Pax1, and Noggin. The remaining cells in the CZ fuse with the adjacent cells in the caudal LZ and form centrum that expresses Sox9 and Col II. This centrum develops further into the vertebral body by expressing bone morphogenetic protein (BMP). Thus, one complete vertebra consists of two somites to interact properly with each other in order to develop normally. The nucleus pulposus will develop inside the annulus from notochord that does not deteriorate.⁷

The patterned formation of cartilage into annulus and nucleus is dependent on gene expression, seen in chondrogenic tissues relative to nonchondrogenic tissues. This is accomplished by alternative splicing of mRNA, producing procollagen II and collagen IX. Sclerotomal cells differentiate into chondrocytes in vertebral bodies when they start producing short type IX collagen. Cells destined to become cartilage express procollagen alpha II, and cells destined to become bone have a longer structural form of type II procollagen that results in the characteristic hardness and structural relationships of vertebral body and disk.

Ossification Stage

Two primary ossification centers are found at each spinal level, one in the centrum of the future vertebral body and other in the vertebral arch. This typically begins in the midthoracic spine and then progresses in a cranial-caudal direction.⁸ Each vertebra is formed from an adjacent cranial and caudal sclerotome. The fusion of these two constitutes a centrum, the embryological precursor to the vertebral body.⁹ Recent discoveries in the hox and pax genes have elucidated their contributions in this matter. Five secondary ossification centers form after birth: transverse processes bilaterally, the tip of the spinous process, and the cranial and caudal surface of the vertebral body.

GENETIC INFLUENCE ON SPINAL DEVELOPMENT

Modern advances in laboratory techniques have expanded our understanding of genetic expression and spinal

development, in addition to positional-dependent induction of neurulation. Wnt and/or fibroblast growth factor (FGF) signaling pathways and BMP activity have been implicated in the organization and induction of gastrulation.¹⁰

Lateral/paraxial mesoderm has been recently thought to be the source of endogenous posteriorizing factors (factors that are key in ensuring a dorsal site of neural induction). Wnt plays a key role in posteriorizing the neuroectoderm. Currently, it is still unclear whether overt posteriorization occurs *in vivo* or which endogenous ligand exerts the transforming influence from lateral mesodermal cells.

Wnt8, another signaling molecule, seems to be correlated with neural anteroposterior patterning, where inactivation of Wnt8 function inhibits formation of spinal cord, hindbrain, and the midbrain–hindbrain boundary without disrupting ventrolateral mesoderm formation.

Modern understanding of spinal cord development at a cellular level has also grown considerably.^{10–13} The development of the spinal cord is dependent on the polarized pattern of expression of regulatory genes and a variety of growth factors.¹¹ The notochord has a role in dorsoventral patterning of the neural tube, without the notochord, the floor plate does not form and motoneurons fail to develop. However, when the neural tube is closed, floor plate and motoneurons develop normally without notochord. Hence, polarization of spinal cord takes place during a well-defined temporal window.¹⁰

Dorsoventral Differentiation of the Neuroaxis

The differentiation of neurons along a dorsoventral axis is of vital importance to organization and development of the spinal cord. Dorsoventral polarization of the spine occurs through a combination of dorsalizing and ventralizing signals from dorsal and ventral midline.¹² Diffusion of molecules encoded by gene expression in the notochord and floor plate thus induce position-dependent growth. One vital signal is a product of the SHH that originates from the notochord and floor plate. This signal initially suppresses dorsalizing signals, hence causing more ventralization. When a ventral identity is formed, graded SHH signals cue development of specific neurons and glial cells. Ventral neurons are derived from the ventricular surface of the basal plate where neuroepithelial precursors are located.

These precursors generate postmitotic progenitor cells that will migrate radially and differentiate into motor and interneurons, both express LIM-homeodomain transcription factors. Depending on the local concentration of SHH along the dorsal–ventral axis, the precursors of different type of neurons can be found. Signals from paraxial and surface mesoderm influence regional specificity of motor neuron subtype along anterior–posterior axis. Intracellular effects of SHH signaling are mediated in part by Pax6 a transcription factor.¹¹ Sonic Hedgehog Gene represses Pax6, hence dorsal half of neural tube will have higher concentration of Pax6 establishing a concentration gradient. Pax6 in turn represses expression of transcription factor Nkx2.2. Pax6-positive areas generate somatic motor neurons of the median motor column that express LIM-domain proteins Isl1, Isl2, Lim3 aka Lhx3, and Gsh4 aka Lhx4.¹¹ Precursors from Pax6-negative generate ventral interneurons that express different combinations of Pax2, En1, Evx1, Lim1, Lim3, Gsh4, and Chx10. Nkx2.2-positive areas generate a subset of motoneurons expressing Isl1 but not Isl2 and a population of cells that express Sim1. Glial cells are also derived from precursors in the ventral half of spinal cord. Development of oligodendrocyte progenitor cells depends on SHH signaling. Oligodendrocyte progenitor cells arise from the ventral-most region of Pax6-positive domain at the ventricular zone of spinal cord, the same area that is thought to give rise to somatic motor neurons of the median motor complex.

DEVELOPMENT OF THE VERTEBRAL COLUMN

Development of the vertebral column takes years, as complete ossification of the halves of the vertebral arch by cells migrating adjacent the neural tube will complete approximately at 6 years of life.¹ Somites in a particular sclerotome, the precursor to the vertebral column, divides into a rostral and caudal portion, whereby migration and differentiation are due to signals expressed by the pax and HOX genes.² The cranial aspect of one sclerotome will fuse to the caudal aspect of an adjacent sclerotome, forming a vertebral body.

DEVELOPMENT OF THE SPINAL CORD

In the third week, invagination of the ectoderm differentiates into mesoderm cells, which ultimately differentiates into the notochord. The migration of these cells was recently understood, through modern scientific advances

in cell signaling.¹⁴ Failure of closure of the neural tube results in a common congenital defect, termed spina bifida. The spectrum of presentations of this disease will be discussed next, ranging from an occult defect in the posterior elements (spina bifida occulta) to a herniation of the neural elements and thecal sac through a laminar defect typically presenting in severe neurological deficits.

Week 5 marks the formation of the alar and basal plate, which are proliferations of tissue on the dorsal and ventral neural tube, respectively. The separation between these two plates is the sulcus limitans, which will eventually separate the sensory from the motor tracts. This division will involute by week 6, followed by the formation of white matter tracts by weeks 7 and 8.

■ POSTNATAL MATURATION OF THE SPINE

The spinal canal has obtained its maximum diameter usually by 8 years of age. While ossification centers, as mentioned above, contribute to maturation of the spine, it is the presence of thin chondroepiphyseal regions on the end plates that contributes to the circumferential growth. This growth is evident on imaging as growth plates, which must be distinguished from fracture. Ossification centers may continue to proliferate and differentiate up to 25-year-olds. Neonatal spinal conformation has a predominating kyphosis of the thoracic spine. Secondary curvatures will then develop as the child becomes ambulatory.

Molecular Marker of the Developmental Spine and Spinal Cord

Recent studies show that there are some specific or selective molecular markers of spine and spinal cord tissues in each developmental stage. It is important to be familiar with these markers to have a better understanding of both normal and abnormal development of the spine and spinal cord. Actually, many researchers label these markers of interests with lacZ or enhanced green fluorescent protein *in vivo*, or develop conditional gene expression model using Cre-loxP system and analyze the phenotype.¹⁵⁻¹⁷

■ CONGENITAL MALFORMATIONS OF THE SPINE

Modern advances in genetic techniques have shed light on the pathogenesis of some particularly devastating diseases.

The presence of one congenital spinal deformity should prompt a further diagnostic inquiry, as studies indicate an incidence of 30% to as high as 60% for additional abnormalities.¹⁸ Through the understanding of the pathogenesis, we have gained a more clear understanding of the normal mechanism of development. Classification of congenital malformations of the spine consists of defects of the neural tube, defects of formation and defects of segmentation.

Neural Tube Defects

The period of gestation between 3 and 4 weeks is when neurulation occurs. Disorders in neurulation have an incidence as high as 1 in 1000 live births in the United States.^{19,20} Preindustrial nations lacking adequate folate carry an even higher incidence. Since 1991, the CDC recommends 4 mg of folate per day for pregnant women, and this is credited as the declining incidence in the industrialized world. Mutations in the methylene tetrahydrofolate reductase gene causing a decrease in its activity is thought to be a risk factor for spina bifida in both mother and child.²¹ Other theories point to elevated homocysteine levels, a consequence of low folic acid intake.²²

Spinal dysraphism refers to failure of fusion of posterior midline structures of the spine. Spina bifida is a condition where the posterior, bony arches fail to fuse.^{19,23} This condition is associated with the TIVS7-2 axial mesoderm allele and spina bifida.²¹ Multiple alleles have been discovered in the past 20 years, whose mutation has a predilection for spina bifida.²⁴⁻²⁶

Further classification of spinal dysraphism is delineated by the presence or absence of intact, overlying skin: spina bifida occulta and spina bifida cystica. The incidence of spina bifida occulta occurs in 24% of the normal population, in select studies.^{27,1} Spina bifida cystica includes myelomeningocele, involving herniation of elements through the bony defect and skin, whereas spina bifida occulta is denoted by the presence of cutaneous irregularity or other stigmata, which serve as clues for underlying disease. Various additional neurological conditions may be present in the diagnosis of spina bifida including Chiari malformation, hydromyelia, and tethered cord.

Myelomeningocele are typically closed within 72 hours of delivery to prevent infections, neurological worsening, or death.²⁸ More recent retrospective data suggests that closure on first day of life may have the best chance for reducing the incidence of a neurogenic bladder.²⁹ The goal of the procedure is to re-establish tissue planes (pia-arachnoid, dura, fascia, skin) and obtain a watertight

closure to allow for maximum barrier between the nervous system and surface bacteria. As high as 85% of the time, hydrocephalus is present, and ventriculoperitoneal shunting may be required for wound healing as well as neurologic development.

One alternative to perinatal myelomeningocele closure is intrauterine surgery during gestation. In a recent randomized trial of prenatal versus postnatal repair of myelomeningocele, fewer infants reached a composite primary outcome of death or need for ventriculoperitoneal shunt at 12 months (68% versus 98% need for shunting).³⁰ The overall rate of ventriculoperitoneal shunt placement was less in the prenatal surgery group with superior mental development and motor function at 30 months.

An additional form of spinal dysraphism is a lipomyelomeningocele, which arises from a failure of disjunction between ectoderm and neuroectoderm. The residual fat attaches dorsally on the conus and protrudes through the defect in the posterior elements. Caudal attachments appear as a continuation of the spinal cord, with a lipomatous mass, and an uncommon transitional form is of note, which can make surgical planning difficult.³¹⁻³³

Failure of Development

VATER is a term coined by Quan and Smith in 1972 to describe the clinical presentation of two or more of the following congenital abnormalities: vertebral defects, anal atresia, tracheoesophageal fistula, and radial limb defects.³⁴ Renal defects were added a year later to the list, and while vertebral defects are seen the most often, many other congenital defects are seen in conjunction with the VATER, but with a decreased frequency.

Among the most common abnormalities seen with VATER are Klippel-Feil syndrome, a congenital fusion of one or more of the cervical vertebrae, and Sprengel deformity, a failure of descent of the scapula, leading to an asymmetrically elevated scapula.

The most commonly involved organ system dysfunction in the presence of a diagnosed congenital spinal deformity is the genitourinary system; with an incidence of as high as 20%.³⁵ Other diagnostic clues include a single umbilical artery, which has a higher incidence of congenital malformation and association with VATER/VACTERL.³⁶

The VACTERL/VATER association further recognizes the underlying genetic contribution to the pathogenesis of this disease. VACTERL stands for vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal

anomalies, and limb defects. A diagnosis requires three or more findings and is seen as often as 1 in 10,000 live births.³⁶

The developmental field defect may explain the constellation of findings in which developmental malformations in blastogenesis would affect multiple organ systems. As of yet, there are no single genetic underlying defect to explain these disease entities and as a result are not syndromal.³⁶

The closest to a disease pathway have been shown in animal models where mutations in SHH pathway genes SHH and Gli have led to VACTERL-like phenotypes. In humans, SHH loss of function mutations commonly lead to holoprosencephaly, not seen commonly with VACTERL.³⁶⁻³⁸ Similarly, mutations in HOXD13 and FOXP1, both linked to SHH signaling, have been associated with VACTERL-like defects. Many other syndromes, with known gene mutations, such as Fanconi anemia, Feingold syndrome, Holt-Oram syndrome, and CHARGE^{39,40} syndrome, have similar presentations to VACTERL.⁴¹⁻⁴³

FAILURE OF SPINE DEVELOPMENT

Failure of Formation

Failures of formation are defined as the absence of any structural component of the vertebral body, resulting in a spinal deformity.¹ Hemivertebrae and wedge vertebrae, are common defects that have been observed to contribute to pediatric spinal deformities as well as adults. Hemivertebrae is primarily a failure of formation, but may overlap with defects of segmentation. They can be fully segmented, semisegmented, and nonsegmented.¹ In the case of a semisegmented vertebrae, there is a functional growth plate on one side only. In the nonsegmented vertebrae, there is an absence of a growth plate and the least contribution to deformity.

Failure of Segmentation

Segmentation is known as the division of the paraxial PSM into somites. These somites are arranged symmetrically in pairs alongside the neural tube and will later form sclerotome, dermatome, and myotome. Segmentation occurs shortly after gastrulation (20-35 days after conception). This process continues until a preprogrammed number of somite blocks are formed (33 blocks in humans).⁶ Somitogenesis is a regulated process that begins at the caudal area followed by the rostral area. This process consists of

two signaling processes: the clock and the wavefront. The clock is made up of genes whose expression oscillates with the amount of time it takes for a somite to form (4–6 hours).^{6,44} The wavefront is formed by a signaling gradient from FGF8 in the caudal PSM, which opposes another gradient from retinoic acid in the rostral PSM.⁶

The clock is regulated by the cyclical induction of Notch1 receptor, signaling crucial genes in the PSM cells: delta-like 3 (DLL3), Mesoderm Posterior 2 (MESP2), and Lunatic fringe (LFNG).^{44,45} Besides, Notch signaling is required for somite boundary formation and somites' anterior–posterior identity. DLL3 refines Notch1 signaling by inducing lysosomal degradation of Notch1 proteins. Without it, somite formation and patterning are irregular causing type I spondylocostal dysostosis (SCD).^{44,45} Spondylocostal dysostosis is classified into three types, SCD1, SCD2, and SCD3. They are characterized by rib fusions, rib deletions, hemivertebrae and loss of vertebrae leading to truncal shortening. Spondylocostal dysostosis 2 is classified by the involvement of the thoracic vertebrae with only mild deformity in the lumbar vertebrae. Mesoderm posterior 2 is crucial in somitogenesis of the rostral PSM and in defining the rostrocaudal polarity of the sclerotome. A mutation in that gene would cause SCD 2.⁴⁵ Spondylocostal dysostosis 3 is caused by mutated LFNG. This is characterized by abnormalities in somite formation and anterior–posterior somite identity resulting in severe axial skeletal defects and reduced numbers of caudal vertebrae.⁴⁵ However, only 30% of SCD cases are caused by mutations of these genes,⁴⁶ where DLL3 is the most commonly affected gene.⁴⁵

Failures of segmentation involve two or more adjacent vertebrae. These vertebrae fail to divide, resulting in a partial or complete loss of the growth plate.¹ A block vertebrae forms when an entire vertebrae is involved. Unilateral bar vertebrae occur as an asymmetric rigid fusion of multiple vertebrae, causing asymmetric growth. Failure of segmentation and formation failures surely overlap, as the underlying processes are similar.

Failure of Spine Maturation and Scoliosis

Abnormal spinal curvature as a result of failures of formation and segmentation are the hallmarks of congenital scoliosis (CS). Most commonly, the primary curvature is seen to involve the thoracic spine 64% of the time.⁴⁷ The vast majority of these curves are progressive, giving the poorest prognosis to curves greater than 50° by age of 2 years.⁴⁸ Prior to any surgical decision, diagnostic workup

will demonstrate various associated congenital problems (e.g. VACTERL/VACTER).

Spondylothoracic dysostosis (STD) is another abnormal vertebral malformation disease initially described by Jarcho and Levin.⁴⁹ It differs from SCD by its variability in rib length and alignment and points of intercostal fusion.⁴⁵ Alternatively, STD is classified as the fusion of all ribs at the costovertebral junctions resulting in a crab-like appearance with defective vertebral segmentation and formation defects along the spine.⁵⁰ Spondylothoracic dysostosis is also associated with other anomalies such as imperforate anus, genitourinary abnormalities, diaphragmatic hernia, choanal stenosis, and cleft palate.⁶ Interestingly, STD has a high prevalence rate in people from Puerto Rico, which is thought to be due to a recessive mutation in MESP2 and E103X.⁴⁵

There are two syndromes associated with defective segmentation; Alagille syndrome (AGS) and Klippel–Feil syndrome. Alagille syndrome is an autosomal dominant disease characterized by facial dysmorphism, scarce bile ducts, defective heart, eye, kidney, pancreas, and skeleton.⁵¹ A butterfly vertebra is seen in 22–87% of people affected by AGS.⁴⁵ Mutations of JAG165 are seen in about 70% of patients with this disease. However, haploinsufficiency of JAGGED1 gene has been proposed to be the main mechanism of AGS.⁶ Those with severe renal manifestation have mutations in NOTCH2.⁵²

Klippel–Feil syndrome is a condition with abnormalities of the cervical spine due to faulty segmentation.⁵³ It can be an autosomal dominant, autosomal recessive, or an X-linked condition. This disease is classified into three types, type I in those with severe fusions of many cervical vertebrae, type II in those with only one or two cervical interspaces fused and type III in those with additional fusions in the lower lumbar spine.⁵⁴ First described in 1894,⁵³ it is associated with diverse organ system malformations, namely neural tube defects, thoracic cage abnormalities, pulmonary, cardiovascular and other skeletal anomalies, genitourinary abnormalities, myopathy, neuropathy, and cognitive disorders.⁵⁵ PAX1 and HOX mutations may have a role in developing this disease.⁵⁵ Another gene known as GDF6, which is part of the WW BMP family, is associated with joint and vertebral formation (Table 17.1). Abnormalities in this gene may contribute to the joint fusions in Klippel–Feil syndrome.⁵⁶

Nonsyndromic vertebral malformations due to defective segmentation include CS and idiopathic scoliosis (IS). Congenital scoliosis can be caused by defective formation

Table 17.1: Selected tissues and known associated developmental markers.

<i>Tissues</i>	<i>Molecular markers</i>
Roof plate	BMP, Wnt1, Wnt3a
Notochord	SHH, Foxa2, T
Floor plate	SHH, Foxa2
Somite	Paraxis
Sclerotome	Pax1
Neural tube	Pax3, Pax6, Pax7
Neural crest	P0, Wnt

of vertebrae and defective segmentations. Anomalies of segmentations are unilateral failure of segmentation and bilateral failure of segmentation. Abnormalities of formation would include unilateral complete failure of formation of vertebra resulting in hemivertebra, nonsegmentation, incarceration of vertebra, and unilateral partial failure of formation causing wedge vertebra.⁴⁵ Congenital scoliosis is associated with many abnormalities such as esophageal atresia, tracheoesophageal fistula, diastematomyelia, anal atresia, Sprengel deformity, facial asymmetry and bladder, and cloacal exstrophy.⁵⁷⁻⁵⁹ Genitourinary abnormalities are particularly more frequent (43%) in patients with CS as they both arise from the mesoderm during the fifth week of embryogenesis.⁴⁵ Renal defects are found in 13% of CS patients.⁶⁰ Other causes of the defect include failures of spinal growth, teratogenic agents, and intrinsic genetic abnormalities.¹⁸ Some evidence suggests that organ malformations correspond to the level of the affected vertebrae.⁶¹ Most of the time congenital scoliosis, if left untreated, will result in progression of the disease, leading to a worse prognosis. One condition like this is CS, which is caused by a unilateral failure of vertebral segmentation with contralateral hemivertebrae. During growth of the child, the hemivertebrae that contain epiphyseal plates grow longitudinally, whereas the unilateral unsegmented bar do not grow because of absent epiphyseal plates. This leads to a crankshaft effect, which causes a rapidly progressive scoliosis. The tethering effect of the unsegmented bar on the concavity of the spine growth further aggravates the situation.⁴⁸

Surgery during the first year of life is recommended to manage this disease. Fusion of the spine by combined anterior and posterior arthrodesis has been proven to overcome the crankshaft effect. Caution must be taken to monitor a secondary curve that will result from the

primary CS. The secondary curve will still develop regardless of the fusion of the primary curve. Hence, prophylactic bracing of the secondary curve can be done.⁴⁸

Idiopathic scoliosis is a diagnosis of exclusion with no definite etiology. It is classified into infantile, juvenile, and adolescent scoliosis.⁶² However, a recent research involving 237 families with at least one CS case in each family shows that 17.3% of the sample reported having members with IS.⁶³ This suggests that IS and CS may have a genetic correlation. A gene that was postulated is the CHD7 gene that is associated with the CHARGE syndrome. Seventy percent of CHARGE patients have late-onset IS.⁶⁴

Like all other congenital abnormalities, teratogens have a role in vertebral malformations too. Substances such as alcohol⁶⁵⁻⁶⁷ (cervical fusion), valproic acid (neural tube defects),⁶⁷ and dilantin (not a strong teratogen)⁶⁸ have been associated with vertebral malformations. Uncontrolled maternal diabetes is also implicated in vertebral malformations. It leads to regression of the caudal spine and agenesis of the lower vertebral column.⁶⁹ Some mechanisms of actions include teratogen-induced embryonic cardiac arrhythmia, which causes transient hypoxia and reoxygenation injury, carbon monoxide poisoning causing altered expression of sonic Hedgehog gene and boric acid altering HOX gene expression pattern.⁴⁵

INTRODUCTION

Congenital spinal lesions are involved in congenital malformations of the spine and spinal cord such as spinal dysraphisms and congenital spinal deformities, which are caused by congenitally anomalous vertebral development. The evaluation of these disorders requires an understanding of anatomic and developmental features of the spine. In this chapter, the developmental anatomy of the spine is briefly reviewed. The anatomy and physiology of these congenital spinal lesions are described individually.

EMBRYOLOGY OF THE SPINE AND SPINAL CORD¹⁻³

During the third weeks of gestation, a definitive notochord forms between the ectoderm and endoderm. At the cephalic end of the embryo, the ectoderm immediately above the notochord begins to thicken and differentiate into neuroectoderm, which forms the neural plate. The neural plate then begins to buckle along its midline to

shape the neural groove, walled in by a neural fold on the either side. While this process occurs, a loose collection of intraembryonic mesenchymal cells begins to coalesce into three regions. The most medial becomes a solid mass, the paraxial mesoderm, which is just lateral to the notochord and on its either side. The paraxial mesoderm is an anlage of the skeletal muscle, bone, and skin. By the end of the third week, this mesoderm begins to segment in a cranial to caudal direction. In the somite stage, corresponding to the 30 days of gestation, a total 42–44 somites appear. There are 4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 8–10 coccygeal pairs. Each somite differentiates into three parts, of which the ventromedial cell mass differentiates to form the sclerotomes, destined to form the vertebral bodies. These bilateral ventromedial cells migrate to the mid line and surround the notochord. Each somite separates into a caudal and a cephalic portion, with the cells of the middle portion condensing to form the intervertebral disc (Figs. 18.1A to C).⁴

In the occipitocervical spines, the four sclerotomes corresponding to the three primary roots of the hypoglossal

Figs. 18.1A to C: Somitogenesis in the embryo. Cross-sections of the developing embryo are shown, representing the different stages of patterning in somitogenesis, which takes place between 20 and 30 days of gestation. (A) Prior to formation of the somite segments, the neural plate is folding to eventually form the neural tube, which is the precursor to the adult spinal cord. The tissue that will form somites is unsegmented, and lies to the side of the notochord, which contributes to the intervertebral disks in the adult. (B) Upon segmentation, the somites are formed as a pair of spherical ball of cells on the either side of the future spinal cord. (C) As the somites mature, the sections nearest the gut migrate away to form the sclerotome, the precursors to the vertebral bones. The remaining dermomyotome forms the muscles of the spine, and the dermis in the skin.⁴

nerve fuse to form the occipital bone. The fourth sclerotome of this complex divides into an anterior and a posterior segment. Subsequently, the anterior segment of the most caudal part of the occipital sclerotome and the most cranial segment of the first cervical sclerotome fuse to form the atlas. The anterior portion of the first and second cervical sclerotomes fuses to form the axis. Any congenital deformity in this region is formed not later than this embryological age. Ossification of these bones appears around the eighth week and is completed in the third year of life except for the odontoid tip, which may not ossify until the age of 12.

Simultaneous with development of the cartilaginous skeleton, differentiation of the nervous system progresses. The neural plate begins to take on a tube-like appearance by the end of the third week. During the fourth week, the neural folds that form the sidewalls start to fuse in the middle line to form a true tube. Fusion of the neural tube proceeds simultaneously in a cephalad and caudad direction, closing along its entire length by the end of the fourth week. The size of the neural tube determines the diameter of the developing spinal canal. During the fifth and sixth week, further differentiation of the various parts of the brain and spinal cord occurs.

CONGENITAL ANOMALIES OF THE CERVICAL SPINE

Congenital anomalies have a varied spectrum ranging from benign asymptomatic conditions to those with a

potential for fatal instability. Congenital causes of cervical spine instability are complex because congenital vertebral anomalies of the cervical spine arise from defective somatogenesis. Congenital anomalies of the cervical spine often occur in clusters, which further complicates these cases because more than one congenital anomaly frequently exists in the same patient. Many developmental anomalies of the craniovertebral junction have been described in the literature in a rather confusing fashion and usually as separate entities. However, each anomaly is usually accompanied by others. Any developmental anomaly of this region can be ectodermal, mesodermal, or a combination of these two germ layers. A classification of these anomalies, depending on embryological development, is simple and facilitates understanding of this complex problem² (Table 18.1). The “minor anomaly” consists of a developmental anomaly or anomalies of a single-germ layer, which can be mesodermal or ectodermal. The term “major anomaly” covers a combination of different germ layers.

BASILAR IMPRESSION AND BASILAR INVAGINATION

Basilar impression is defined as upward displacement of the dens into the normal foramen magnum with normal bone, while basilar invagination is a similar displacement due to softening of bones at the base of the skull. Thus, different terms are used according to whether bone is normal or not. With this anomaly, the dens are displaced

Table 18.1: Classification of craniovertebral anomalies.

Minor mesodermal asymptomatic anomalies	Arch anomalies of atlas Arch anomalies of axis Atlanto-occipital articulation anomalies Occipital condyle asymmetries Occipital vertebrae
Minor ectodermal asymptomatic anomalies	Blind dermal sinus Intradural fibrous bands
Minor mesodermal symptomatic anomalies	Occipitalization of atlas Hypoplastic atlas Odontoid hypoplasia Odontoid agenesis Os odontoideum Congenital atlantoaxial instability Basilar impression
Minor ectodermal symptomatic anomalies	Syringomyelia of neighboring cord Arnold-Chiari type I malformation
Major anomalies	Arnold-Chiari type II-III malformation with spinal dysraphism Syringomyelia with basilar impression

cranially through the foramen magnum to encroach the brainstem. It is commonly associated with other anomalies such as Klippel-Feil syndrome (KFS), hypoplastic atlas, and occipitocervical synostosis. It may also accompany systematic disorders such as achondroplasia, osteogenesis imperfecta, and Morquio-Brailsford syndrome.

A plain lateral X-ray, with odontoid views, is a good place to start (Fig. 18.2). Chamberlain's line is drawn between the posterior hard palate and the posterior edge of the foramen magnum. The normal position of the dens is between 1 mm below this line and as much as 0.6 mm above it. McGregor's line is the line drawn from the posterior hard palate to the base of the occiput. Protrusion of the tip of the dens greater than 4.5 mm above this line is abnormal. McRae's line extends from the basion to the posterior lip of the foramen magnum. Protrusion of the tip of the dens above McRae's line is indicative of basilar invagination. A plain computed tomography (CT) scan with sagittal reconstructions can also document this, but magnetic resonance imaging (MRI) provides more information.

■ OCCIPITALIZATION OF THE ATLAS

Occipitalization is a congenital synostosis of the atlas to the occiput, which is a result of failure of segmentation and separation of the most caudal occipital sclerotome

and the first cervical sclerotome during the first few weeks of fetal life.³ There may be varying degrees of bony fusion between atlas and occiput. In a majority of cases, assimilation occurs between the anterior arch of the atlas and the anterior rim of the foramen magnum and is associated with other skeletal malformations such as basilar invagination, occipital vertebra, spina bifida of atlas, or fusion of the C2-3 vertebrae (KFS).

■ ARNOLD-CHIARI MALFORMATION

Arnold-Chiari malformation is a malformation of the brain. It consists of a downward displacement of the cerebellar tonsils through the foramen magnum, sometimes causing noncommunicating hydrocephalus as a result of obstruction of cerebrospinal fluid outflow. Arnold-Chiari malformation is classified into types I, II, III, and IV (Table 18.2).

The most widely accepted pathophysiological mechanism by which Arnold-Chiari type I malformations occur is by a reduction or lack of development of the posterior fossa as a result of either congenital or acquired disorders. Congenital causes include hydrocephalus, craniosynostosis (especially of the lambdoid suture), hyperostosis (e.g. craniometaphyseal dysplasia, osteopetrosis, erythroid hyperplasia), X-linked vitamin D-rickets, and neurofibromatosis type I.

Fig. 18.2: McRae line is a radiographic line drawn on a lateral radiograph of skull, joining the anterior (basion) and posterior (opisthion) aspects of foramen magnum. Normal position of the tip of dens is 5 mm below this line. If the tip of the dens migrates above this line it indicates the presence of basilar invagination. Chamberlain's line is drawn between the posterior hard palate to the posterior edge of the foramen magnum. If the dens is more than 3 mm above this line, the patient has basilar invagination. The McGregor line is a modification of the Chamberlain line and is used in the evaluation of basilar invagination when the opisthion could not be identified on plain radiographs. It refers to a line connecting posterior edge of the hard palate to the most caudal point of the occipital curve. If the tip of the dens lies more than 4.5 mm above this line it is indicative of basilar invagination.

Table 18.2: Classification of Arnold-Chiari malformation.

Type	Presentation
I	<ul style="list-style-type: none"> • A congenital malformation • Herniation of cerebellar tonsils • Tonsillar ectopia of more than 3 mm below the foramen magnum • Syringomyelia of cervical or cervicothoracic spinal cord can be seen • Sometimes the medullary kink and brainstem elongation can be seen
II	<ul style="list-style-type: none"> • Usually accompanied by a lumbar myelomeningocele or lumbosacral spine with tonsillar herniation below the foramen magnum • As opposed to the less pronounced tonsillar herniation seen with Arnold-Chiari I, there is a larger cerebellar vermian displacement • Low-lying torcular herophili, which is important for distinction from Dandy-Walker syndrome, tectal beaking and hydrocephalus with consequent clival hypoplasia are classic anatomic associations • Colpocephaly may be seen due to the associated neural tube defect
III	<ul style="list-style-type: none"> • Associated with an occipital encephalocele containing a variety of abnormal neuroectodermal tissues • Syringomyelia and tethered cord as well as hydrocephalus are also seen
IV	<ul style="list-style-type: none"> • Characterized by a lack of cerebellar development in which the cerebellum and brainstem lie within the posterior fossa with no relation to the foramen magnum. Associated with hypoplasia

Figs. 18.3A and B: Atlantoaxial instability. (A) Intact odontoid. Flexion. Forward sliding of the atlas with an increased atlas-dens interval (ADI) and decreased space available for the spinal cord (SAC). (B) Os odontoideum. Forward sliding of the atlas with reduction of the SAC, but no change in ADI.

CONGENITAL ANOMALIES OF THE ATLANTOAXIAL JOINT

The congenital disorders involving the atlanto-odontoid articulation include hypoplasia or absence of the odontoid, occipitalization of the atlas as well as incompetence or absence of the transverse axial ligament, but the end result is narrowing of the spinal canal and impingement of the neural elements. Motion of the atlantoaxial articulation is usually accentuated in patients with bony anomalies of the occipitocervical junction. If an associated synostosis of C2-3 with occipitalization of the atlas exists, the additional stress on the atlantoaxial articulation may eventually lead to significant instability.

Congenital laxity of the transverse atlantal ligament is a diagnosis of exclusion suggested by the clinical occurrence of atlantoaxial dislocation without a predisposing cause such as history of trauma or congenital anomaly. This is a usually common in patient with Down's syndrome.

Radiological appearance of congenital atlantoaxial instability is important. The atlas-dens interval (ADI) is the space seen on the lateral X-ray between the anterior aspect of the dens and the posterior aspect of the anterior ring of the atlas (Figs. 18.3A and B). In children, the ADI should be no greater than 4.0 mm, particularly in flexion where the greatest distance can be noted. The amount of space available for the spinal cord (SAC) should be evaluated for a patient with os odontoideum or absent odontoid (Fig. 18.2). This is accomplished by measuring the distance from the aspect of the odontoid or axis to the nearest posterior structure (foramen magnum or the posterior ring of the atlas).

CONGENITAL ANOMALIES OF THE ODONTOID

Anomalies of the odontoid include complete aplasia, hypoplasia, and os odontoideum. All three conditions can produce symptoms and serious neurologic sequelae as a result of atlantoaxial instability. In developmental anatomy of the odontoid,⁵ summit ossification center for odontoid appears at 3–6 years and fuses with the odontoid by 12 years and basilar synchondrosis fuses by age of 7 years, on average. Subdental synchondrosis scar may remain as a remnant of this fusion. Two separate centers of the odontoid appear by the fifth fetal month and fuse with each other by the seventh fetal month. Synchondrosis between odontoid and neural arch and synchondrosis between odontoid and body fuses at 3–6 years. In young patients with incompletely ossified odontoid, a diagnosis of hypoplasia may be made in error. Hypoplasia of odontoid may be seen in conjunction with dysmorphic conditions such as achondroplasia or spondyloepiphyseal dysplasia. Os odontoideum, the most common anomaly, is currently believed to be traumatic in origin. In os odontoideum, the odontoid is an oval or round separated from the axis vertebra by a transverse gap. In imaging studies, a space is present between the body of the axis and a bony ossicle. The free ossicle of os odontoideum usually is half the size of a normal odontoid and is oval or round with smooth, sclerotic borders. Watanabe et al.⁶ reported that sagittal plane rotation angles, which calculated the difference of the atlantoaxial angle between the flexion and extension position is calculated, were more than 20°; or the instability index, which obtained from the change of SAC from flexion to extension, was more than 40% correlated with neurological signs and symptoms in patients with os odontoideum. It is important to evaluate the instability in congenital anomalies of the odontoid.

KLIPPEL-FEIL SYNDROME

Klippel-Feil syndrome, the congenital synostosis of the cervical vertebrae or brevicollis anomaly, refers to segmentation defects or fusion of the cervical spine. Short neck, low posterior hairline, and limitation of the movement of the head or the neck are the commonly described clinical features. The typical disorder results from a failure of the normal segmentation of the somites during weeks 3–8 of gestation. Growth differentiation factor (*GDF*) 6 and *GDF*3 gene mutations that cause KFS likely lead to a reduction in functional protein. While the *GDF*6 and *GDF*3 proteins

are involved in bone growth, and the *GDF*6 protein plays a role in the formation of vertebrae, it is unclear how a shortage in these proteins leads to incomplete separation of the vertebrae, specifically the cervical vertebrae, in patients with KFS.⁷ Associated abnormalities may include scoliosis (seen in 60%), spina bifida, Sprengel deformity (seen in 33%), genitourinary abnormalities such as malformed kidneys (occurs in 33%), anomalies of the ribs, cleft palate, respiratory problems, and heart malformations. The disorder also may be associated with abnormalities of the head and face, skeleton, sex organs, muscles, brain and spinal cord, arms, legs, and fingers.

The Klippel-Feil classification⁸ characterizes three different types of KFS showing specific morphologic features: type I displays a massive fusion of many cervical and upper thoracic vertebra with synostosis; in type II, the fusion is at only one or two interspaces, with hemivertebrae, occipitalization of the atlas, and other abnormalities in the cervical spine; and type III shows cervical fusions associated with lower thoracic or lumbar fusion. Most of the skeletal anomalies are found in type II of KFS. Syndrome anomalies dominate in type I KFS. Type II KFS with isolated synostosis of the cervical spine has the lowest risk for scoliotic development, whereas types I and III show progression of the curve.⁹

Samartzis et al.¹⁰ reported that specific fused patterns of the cervical spine in patients with KFS were associated with cervical spine related clinically significant symptoms. Axial symptoms of neck/headache, neck pain, and neck stiffness are the predominant symptoms in symptomatic KFS patients and are largely noted in patients who present with a single fused cervical segment. KFS patients with multiple congenitally fused segments are associated with a higher incidence and risk of developing radiculopathy or myelopathy, which is noted later in adolescence.

CONGENITAL STENOSIS OF THE CERVICAL SPINAL CANAL

Congenital stenosis means that the space in their spinal canal from birth is smaller than in most people. In many instances, the term spinal stenosis is used for actual spinal cord compression on diagnostic studies relative to the dimension of the cord for that person at other “normal” segments. The anteroposterior (AP) diameter of the normal adult male cervical canal is about 17 mm. Absolute cervical stenosis is associated with an AP diameter of less than 10 mm, whereas diameters of 10–13 mm are relative stenosis.

Fig. 18.4: The spinal canal to vertebral body ratio is the distance from the midpoint of the posterior aspect of the vertebral body to the nearest point on the corresponding spinolaminar line (A) divided by the anteroposterior width of the vertebral body (B).¹¹

Pavlov ratio (Ratio = AP diameter of cervical canal/width of cervical vertebral body) should be approximately 1.0 (Fig. 18.4). Less than 0.85 indicates stenosis, and less than 0.80 is a significant risk factor for myelopathy, radiculopathy, or both due to relatively minor spondylosis pathology or trauma neurologic injury in relatively minor trauma.¹¹ However, Blackley et al.¹² examined the reliability of this method using plain lateral radiographs of unknown magnification and CT scans and found that a poor correlation between the true diameter of the canal and the ratio of its sagittal diameter to that of the vertebral body. Therefore, CT scans or MRI is needed to evaluate the spinal canal of the cervical spine.

SPINAL DYSRAPHISMS

Congenital abnormalities of the spine and spinal cord are referred to as spinal dysraphisms. Spinal dysraphisms can be broadly categorized into open and closed types.¹³⁻¹⁵ In an open spinal dysraphism, there is a defect in the overlying skin, and the neural tissue is exposed to the environment. In a closed spinal dysraphism, the neural tissue is covered by skin. Closed spinal dysraphisms can be further subcategorized on the basis of the presence or absence of a subcutaneous mass.¹⁶

Congenital malformations are mostly due to the defective closure of the caudal neuropore at the end of week 4. The defects will involve the tissue overlying the spinal cord. Involving the spinal cord and vertebral arches are called spina bifida. Spina bifida occulta is a defect in the vertebral arch (neural arch) resulting from failure of the halves of the vertebral arch to grow normally and fuse in the median plane. Spina bifida cystica is a protrusion of the spinal cord and/or meninges through the defective neural arch. Spinal dermal sinus representing the area of closure of the caudal neuropore at the end of week 4 may exist. It is the last place of separation between the ectoderm and the neural tube. The dimple may be connected by a fibrous cord with the dura mater.

Simple dysraphic states consist of intradural lipoma, filar lipoma, tight filum terminale, persistent terminal ventricle, and dermal sinus. A dermal sinus is an epithelial lined fistula that connects neural tissue or meninges to the skin surface. It occurs most frequently in the lumbosacral region and is often associated with a spinal dermoid at the level of the cauda equina or conus medullaris.

Neurenteric cysts are found within the spinal canal and are lined by mucin-secreting, cuboidal or columnar epithelium resembling the gastrointestinal tract. Embryologically, neurenteric cysts may be due to endodermal differentiation of primitive-streak remnants, possibly related to incomplete regression of the neurenteric canal.

Diastatomyelia is characterized by a localized longitudinal separation of the spinal cord with an interposed septum. The two hemicords are usually symmetric, although the length of separation is variable. There are two types of diastatomyelia. In type I, the two hemicords are located within individual dural tubes separated by an osseous or cartilaginous septum. In type II, there is a single-dural tube containing two hemicords, sometimes with an intervening fibrous septum.¹⁷ Diastatomyelia can present clinically with scoliosis and tethered cord syndrome. Categorization of spinal dysraphisms is summarized in Table 18.3.¹⁸

SPINAL MENINGEAL CYST

The classification of spinal meningeal cysts in the literature is indistinct, confusing and in certain categories histologically misleading. Nabors et al.¹⁹ propose a classification comprising three categories: type I: extradural meningeal cyst without neural tissue. Type Ia: extradural spinal arachnoid cyst. Type Ib: sacral meningocele, type II:

Table 18.3: Summary of spinal dysraphisms.*1. Open spinal dysraphisms: not covered by intact skin*

Myelocele	Neural placode flush with skin surface
Myelomeningocele	Neural placode protrudes above skin surface
Hemimyocele	Myelocele associated with diastematomyelia
Hemimyelomeningocele	Myelomeningocele associated with diastematomyelia

*2. Closed spinal dysraphisms: covered by intact skin**(1) With a subcutaneous mass*

Lipomyelocele	Placode-lipoma interface within the spinal canal
Lipomyelomeningocele	Placode-lipoma interface outside of the spinal canal
Meningocele	Herniation of cerebrospinal fluid-filled sac lined by dura
Terminal myelocystocele	Terminal syrinx herniating into posterior meningocele
Myelocystocele	Dilated central canal herniating through posterior spina bifida

*(2) Without a subcutaneous mass**Simple dysraphic states*

Intradural lipoma	Lipoma within the dural sac
Filar lipoma	Fibrolipomatous thickening of filum
Tight filum terminale	Hypertrophy and shortening of filum
Persistent terminal ventricle	Persistent cavity within conus medullaris
Dermal sinus	Epithelial lined fistula between neural tissue and skin surface

(3) Complex dysraphic states

Dorsal enteric fistula	Connection between bowel and skin surface
Neurenteric cyst	More localized form of dorsal enteric fistula
Diastematomyelia	Separation of cord into two hemicords
Caudal agenesis	Total or partial agenesis of spinal column
Segmental spinal dysgenesis	Various segmentation anomalies

extradural meningeal cyst containing neural tissue, e.g. Tarlov cyst and type III: spinal intradural meningeal cysts or intradural spinal arachnoid cyst. The diverticula of dura and/or herniation of arachnoid through a dural defect are thought to be an etiology of the spinal meningeal cyst.

CONGENITAL SPINAL DEFORMITIES

Congenital spinal deformities are caused by congenital anomalies of the spine due to abnormal vertebral development and result in growth asymmetry. The vertebral anomalies may be present at birth, but the deformity resulted from an abnormal spinal curvature may not be diagnosed until later in life. These anomalies are divided into three major categories: scoliosis, kyphosis, and lordosis. Combinations such as lordoscoliosis and kyphoscoliosis are common.

Although there are many types of vertebral dysmorphology observed in congenital scoliosis, they result from abnormal segmentation of the vertebral precursors, called somites. A congenital spinal deformity has a very high frequency of associated anomalies both within and outside the spine. Up to 60% of patients have one or more associated anomalies.²⁰ The most common associated lesion is spinal dysraphism. The prevalence of dysraphic lesions is approximately 40%.²¹ Various other spinal abnormalities may be seen, including Arnold–Chiari malformation, Klippel–Feil anomaly, syringomyelia, diplomyelia and intraspinal tumors. These lesions may or may not be associated with a cutaneous hairy patch, a nevus or a detectable neurologic deficit. Urogenital and cardiac anomalies occur in 20% and 10–15% of cases, respectively. Studies have estimated a 30–60% incidence of additional abnormalities in children with an existing congenital spinal deformity.²² The main associated defects involve

the VACTERL syndrome. VACTERL is an abbreviation with each letter representing an associated defect; vertebral anomalies, imperforate anus, cardiac abnormalities, tracheoesophageal fistula, renal dysplasias, and limb malformations.²³ The patients with congenital spinal deformities should be evaluated for these associated anomalies.

The interaction of environmental factors and the genes that play a role in regulation of somite segmentation is thought to be disrupted in congenital spinal deformities. The cycling of genes including notch pathway is thought to regulate the periodic activation of the notch signaling pathway, which would be required for the segmentation process. Mutations in two genes in the notch family have been identified with human defects of vertebral deformities; delta-like 3 in spondylocostal dysostosis,²⁴ and jagged 1 in Alagille syndrome.^{25,26} Spondylocostal dysostosis is a severe vertebral defect syndrome that is characterized by generalized vertebral anomalies, rib fusions, and congenital kyphoscoliosis. Alagille syndrome is a congenital, multiorgan disorder that is also associated with multiple vertebral anomalies and liver and heart problems. Somite genes that control or influence somitogenesis, including those in the notch family are currently

being examined in human spinal defects.⁴ Hypoxia, carbon monoxide, fetal alcohol syndrome, hyperthermia have been reported to be an environmental factor associated with congenital spinal deformities. The disturbances in the normal development of the spine that result in congenital spinal deformities may be caused by teratologic agents or can be on a genetic basis.

The congenital spinal anomalies result from either failure of formation, failure of segmentation, or a combination of abnormalities of the anlage of the vertebral column. The anomaly and where it is in the vertebral ring determine the deformity.

FAILURE OF FORMATION

The most common type of failure of formation anomaly is a hemivertebra. This is where a portion of the vertebra is missing resulting in a small, triangular shaped “half vertebra” or hemivertebra. Hemivertebra is a wedge-shaped vertebra with one pedicle. It can be subdivided as fully segmented, semisegmented, and unsegmented, according to the relation with the cranial and caudal adjacent vertebral bodies (Figs. 18.5A to E).

Figs. 18.5A to E: Failures of formation; various types of hemivertebrae and wedge vertebra. A hemivertebra represents a complete unilateral failure of vertebral formation. The hemivertebra may be fully segmented (A), semisegmented (B), nonsegmented (C) and incarcerated (D). Fully segmented or nonincarcerated hemivertebra have a normal intervertebral disc superior and inferior to the involved vertebral anomaly. Semisegmented hemivertebra is fused to the neighboring vertebra on one side with one open intervertebral disc space on the opposite side. Nonsegmented spaces superior or inferior hemivertebra are fused to both vertebrae with no intervertebral disc to the involved vertebral anomaly. An incarcerated hemivertebra is nested in a niche in a neighboring vertebra; the pedicle alignment remains straight, and a usual rule there is minimal scoliosis. A wedge vertebra represents a partial failure vertebral formation on one side (E).

Nakajima et al.²⁷ reported the types of laminae of formation failure and classified them into bilamina and hemilamina, based on the number of pedicles of the anomalous vertebra. Laminae with one pedicle are sub-classified into fully segmented hemilamina, semisegmented hemilamina, spina bifida, and incomplete lamina, which are defined as a nearly normal bilamina with only one pedicle.

Wedge-shaped vertebrae result from partial unilateral maldevelopment, but there is usually an entire disc above and/or below. Wedge vertebrae are defined as wedge-shaped vertebrae with one pedicle on each side. Because wedge vertebrae exhibit two pedicles, they inevitably exhibit a bilaminar posterior structure. Kawakami et al.²⁸ proposed that wedged vertebra might be defined as a wedge-shaped vertebra in which the height of one side decreases by more than 50% of the opposite side, or whose adjacent cranial or caudal vertebra is almost normal shape, not wedge-shaped if the height on the one side of the wedge-shaped vertebra decreases less than 50% of the opposite side.

If the defect formation is symmetrical, several lesions are possible, including complete aplasia of the vertebra, aplasia of the vertebral body, or aplasia of the posterior elements. Complete or incomplete failure of midline fusions of the paired somites can result in butterfly vertebrae. Since, this type of anterior formation failure exhibits two pedicles, their posterior components are bilamina despite variations of the asymmetrical shape. An asymmetrical partial defect of the vertebral body often causes scoliosis.

Hemimetameric segmental displacement or shift is a multilevel pattern of vertebral anomalies characterized by two contralateral hemivertebrae separated by at least one normal vertebra.

FAILURE OF SEGMENTATION

Defective segmentation of the vertebrae can be symmetrical or asymmetrical. If a sclerodermal cleft fails to develop, fused vertebral bodies result. This may be unilateral, leading to an anterolateral bar, or bilateral, producing two blocked vertebrae, which are circumferentially unsegmented vertebrae. Unilateral unsegmented vertebral bars are caused by the failure of segmentation only on the left or right side of the spine. In the involved area of the spine there is absent or abnormal growth potential due to an area of missing bone (formation defect) or missing growth

Figs. 18.6A and B: Failures of segmentation; (A) block vertebra and (B) unsegmented bar. Block vertebra is a bilateral failure of segmentation with fusion of the intervertebral disc between the involved vertebrae. A unilateral unsegmented bar is a vertebral bar fusing both intervertebral disks and facets on one side; rib fusions are frequently present on the same side as the bar.

plates (segmentation defect). This results in an area of absent growth potential in the vertebral ring, and the growth in the remainder of the vertebral ring disrupts the normal alignment of the spine, producing different types of deformities (Figs. 18.6A and B). Unilateral unsegmented bar with contralateral hemivertebrae results from combination of abnormalities of the anlage of the vertebral column.

These anatomical changes of congenital spinal deformity have been classified by plain X-ray images, which were comprised mainly of vertebral bodies. The radiographic findings of front and lateral, plain X-ray images of congenital spinal anomalies sometimes result in difficulty in classifying the deformities when severe twisted three-dimensional (3D) curves are present. Kawakami et al. reported a new approach to 3D classification for congenital vertebral anomalies using the 3D CT images.²⁸ Analysis based on the perspective of 3D imaging might result in understanding the etiology and embryology. Careful individualized follow-up is necessary for the successful treatment of the patient with congenital spinal deformity.

CONGENITAL SCOLIOSIS

Congenital scoliosis is a lateral curvature of the spine caused by developmental vertebral anomalies that produce a lateral longitudinal imbalance in growth of the spine. Deformity can occur in any area of the spine, from the cervical to the lumbosacral region. The propensity for

progression is related especially to the type of anomaly, but also the growth rate of the patient. The most progressive type of scoliosis is that due to a unilateral unsegmented bar with a contralateral hemivertebra. The next most severely progressive type of curve is an isolated unsegmented bar, followed by scoliosis caused by two consecutive free hemivertebrae on the convex side.

CONGENITAL KYPHOSIS

Congenital kyphosis is defined as an abnormal sagittal curvature of the spine due to congenital vertebral anomalies that result in sagittal growth asymmetry. Failure of formation is usually included in the congenital kyphosis and nearly always occurs in the thoracic and thoracolumbar spine (Figs. 18.7A and B). More common are anterior symmetrical defects of segmentation, caused by failure of the mesoderm to cleft into somites and producing a congenital kyphosis (Figs. 18.7A and B). This type is most common in the lumbar and thoracolumbar areas.

There are two types of spine dislocation—sagittal plane dislocation only and both sagittal and rotatory subluxation with subsequent rotatory displacement of the spinal canal²⁹—observed in congenital kyphosis, known as either congenital lumbar kypholisthesis, rotatory/congenital dislocation of the spine, or segmental spinal dysgenesis.

CONGENITAL LORDOSIS

Congenital lordosis, which is essentially always caused by failure of segmentation of the posterior arch structures in the presence of active growth anteriorly, is exceedingly rare. Most patients who have congenital lordosis also have some degree of scoliosis. The deformity associated with congenital lordosis is usually progressive. When the deformity occurs in the thoracic spine, it can severely compromise pulmonary function by markedly limiting intrathoracic volume.

CONGENITAL SPONDYLOLISTHESIS

Spondylolisthesis is from spondylos and listhesis, meaning movement or slipping, and refers to the slipping forward of one vertebra on the next caudal vertebra. Congenital or dysplastic spondylolisthesis is classified as type I (Figs. 18.8A and B).^{30,31} This is divided into following three types.

Figs. 18.7A and B: Type of congenital kyphosis. (A) Anterior failure of segmentation. (B) Anterior failure of formation.

Subtype IA

There is a congenital deficiency in the L5–S1 facet joints that allows forward slipping of L5 on S1. Hypoplasia or dysplasia of the superior sacral segment most commonly manifests as a combination of spina bifida occulta of S1 and deformity of the sacral articular processes. There is concomitant deformity of the inferior articular processes of L5. The inferior articular processes of L5 parallel the horizontally oriented sacral facets. This axial orientation and unstable anatomic situation may lead to forward slippage. There is no defect or elongation of the pars.

Subtype IB

In this type, the articular processes have a sagittal mal-orientation, but the neural arch is usually intact. The intact neural arch usually prevents high degrees of forward slippage in this type. When the articular processes are sagittally oriented, there is no bone on bone contact in flexion. The soft tissues of joint capsules bear the force of flexion and allow forward subluxation. In some patients, in whom the articular processes are parallel to each other, may also allow spondylolisthesis.

Subtype IC

All other congenital anomalies of the lumbosacral junction are associated with spondylolisthesis. Congenital kyphosis is the most common anomaly.

CONGENITAL SPINAL STENOSIS

Congenital stenosis is present at birth as part of a malformation and divided into idiopathic and associated with a

Figs. 18.8A and B: Congenital spondylolisthesis. (A) Type IA congenital spondylolisthesis where the facet joints have a horizontal orientation, making them ineffective at preventing forward displacement of the lumbar vertebra above. (B) Type IB congenital spondylolisthesis caused by the articular processes having a sagittal malorientation.

developmental disorder, such as achondroplasia, hypochondroplasia, Morquio's mucopolysaccharidosis, and Down's syndrome. Congenital spinal stenosis often is asymptomatic until middle age, when secondary degenerative changes develop. The sagittal diameter of the lumbar spinal canal has its maximum development between 12th and 32nd week of intrauterine life and at birth has already reached 70% of its normal grown-up dimensions at the L1-L4 level. Therefore, prenatal factors influence the growth of the spinal canal. Generally, congenital stenosis is caused by an anomaly in the vertebral arch such as malorientation of the facet joints, hypoplasia of the laminae or pedicles. Congenitally, stenotic patients have a shorter pedicular length and as a result a smaller cross-sectional spinal canal area, compared with asymptomatic age- and sex-matched subjects. However, congenital lumbar stenosis has not been clearly defined radiographically.³² In achondroplasia, the vertebral disproportion is caused by a premature fusion of the vertebral body's chondrification centers with those of the vertebral arch, during the embryo's development. This results in a reduced bony spinal diameter.

CONCLUSION

This chapter has focused on anatomy of congenital spinal anomalies, which may be associated with development of the spine. Physicians should be aware of these common

types of congenital spinal anomalies as well as identify possible associated abnormalities in other systems thorough physical examination.

KEY POINTS

- Anatomies and some physiologies of congenital spinal lesions, which are involved congenital malformations of the spine and spinal cord caused by congenitally anomalous vertebral development, were reviewed.
- Physicians treating patients with congenital spinal lesions should have an understanding of normal embryologic development as well as common associated abnormalities.
- As congenital cervical lesions, the anatomy and physiology of basilar impression, occipitalization of the atlas, congenital stenosis, Arnold-Chiari malformation, congenital anomalies of the atlantoaxial joint and odontoid and KFS were reviewed.
- Anatomies and categorization of spinal dysraphisms are summarized in this chapter.
- Congenital spinal deformities are caused by congenital anomalies of the spine due to abnormal vertebral development and result in growth asymmetry. A new classification of congenital scoliosis based on the perspective of 3D imaging is needed to understand the etiology and embryology, as well as to determine an operative strategy.

This article clearly demonstrated that sagittal plane rotation angles, or the instability index correlated with neurological signs and symptoms in patients with os odontoideum. The authors point out that it is important to evaluate the instability in congenital anomalies of the odontoid.

Samartzis DD, Herman J, Lubicky JP, et al. Classification of congenitally fused cervical patterns in Klippel-Feil patients: epidemiology and role in the development of cervical spine-related symptoms. *Spine*. 2006;31:E798-804.

The authors demonstrated that specific fused patterns of the cervical spine in patients with KFS were associated with cervical spine-related clinically significant symptoms, and that axial symptoms of neck/headache, neck pain,

and neck stiffness are the predominant symptoms in symptomatic KFS patients and are largely noted in patients who present with a single fused cervical segment.

Rufener SL, Ibrahim M, Raybaud CA, et al. Congenital spine and spinal cord malformations—pictorial review. *Am J Roentgenol*. 2010;194:S26-S37.

This article showed beautiful pictures of spinal dysraphisms in the text and the categorization is easy understandable.

Kawakami N, Tsuji T, Imagama S. Classification of congenital scoliosis and kyphosis. A new approach to the three-dimensional classification for progressive vertebral anomalies requiring operative treatment. *Spine*. 2009;34:1756-65.

The authors reviewed three-dimensional (3D) computed tomography (CT) images of congenital spinal deformities and proposed a new classification based on the information obtained. They clearly illustrate the limitations of two-dimensional classification, to summarize the clinical significance of 3D analysis of congenital vertebral anomalies, and to propose a new 3D classification of congenital vertebral anomalies.

Congenital Anomalies of the Cervical Spine

INTRODUCTION

Congenital abnormalities of the cervical spine are variable in their clinical presentation, extent of anatomic malformation, and potential consequences for the patient. Most lesions are identified before adulthood, but some remain undetected until later in life. They can be asymptomatic and discovered incidentally; present with neck deformity, pain, neurologic symptoms; or present with acute or chronic myelopathy. They can be found in isolation as sporadic, solitary cases, or in combination with other cervical anomalies. Patients with genetic syndromes will have other spinal, skeletal, or multiorgan anomalies. Not infrequently, cervical anomalies may initially be misinterpreted as a traumatic injury (but will eventually be differentiated with the use of additional detailed imaging studies) in conjunction with a lack of soft tissue swelling and acute neurologic deficits and lesser degrees of vertebral subluxation.^{1,2} Treatment is also variable, ranging from no intervention to continued clinical and radiographic vigilance to urgent attention. Surgical intervention is typically reserved for those patients whose lesions are causing or have caused neurologic injury, chronic pain, or spinal deformity or whose injuries place them at high risk for developing any of these consequences. Treatment is also dependent on the age of the patient, his or her level of activity, and osseous development as it pertains to surgical fixation.

This chapter will focus on providing the reader with a comprehensive review of the numerous congenital osseous

anomalies of the cervical spine as they occur in isolation, with other anomalies, and as part of a syndrome. In addition, we will summarize the key steps in embryologic development of the different regions of the cervical spine. Treatment and outcomes will be briefly discussed where appropriate, but detailing the technical nuances and outcomes of surgical treatment for the various disorders is beyond the scope of this chapter. Furthermore, we will not discuss congenital anomalies that are more related to the development of the spinal cord,³ such as dermal sinus tracts,³⁻⁵ neurenteric cysts,⁶ myelocystoceles,⁷ and meningoceles,⁸ but will provide the reader with several references and emphasize that it is not uncommon for spinal cord and spinal column anomalies to coexist.

EPIDEMIOLOGY OF CONGENITAL DISORDERS

The incidence of congenital disorders is difficult to quantify because many congenital abnormalities of the cervical spine are asymptomatic and the true incidence is likely to be largely underreported. It has been estimated that as many as 5% of fetuses have vertebral anomalies, but the reported incidence in the general population is much lower.⁹ Some authors have reported that congenital anomalies of the cervical spine occur in approximately 1 in 40,000–42,000 births with a slight female predominance.^{10,11} Congenital fusions can occur at any level of the

Figs. 19.1A and B: (A) The ventral aspect of the somite is the sclerotome that becomes an aggregate of cells destined to become the skeletal system. (B) The process of resegmentation forms the vertebral body when the rostral half of one somite migrates and joins with the caudal half of the somite above.

cervical spine, although 75% occur in the region of the first 3 cervical vertebrae. The incidence of Klippel–Feil syndrome (KFS), which is described in greater detail later, is estimated to be approximately 1:40,000–42,000 births.^{10,12} Congenital fusion of the atlas with the occiput is one of the most common anomalies of the craniovertebral junction (CVJ), with a prevalence rate from 0.08% to 2.8% in the general population.¹³

EMBRYOLOGY AND DEVELOPMENT OF THE CERVICAL SPINE

Embryology is of paramount importance when it comes to understanding any type of congenital anomaly. The etiology of these disorders usually involves defects in some point of embryological development and malformation of tissues derived from all three embryologic layers. It is a highly complex process and is still not completely understood.

The human spine starts its embryological development on gestational day 16 while the embryo is within its triploblastic stage and shaped as a disk. The notochord is formed in the midline at the rostral end of the embryo by mesoblastic cells that migrate cranially from the primitive knot between the ectoderm and the endoderm. The presence of the notochord induces the overlying ectodermal cells to start the process of thickening and formation of the

neural plate. This plate's sides will then start to curl and, on day 21, will eventually fuse forming the neural tube, the future spinal cord. This process is called primary neurulation. The notochord and the primitive streak are strong inductive tissues and play a critical role in induction and development of future organs.

On either side of the notochord and the neural tube, mesodermal tissue condenses and—at about day 20—becomes segmented into four occipital and eight cervical somites, paired cuboidal structures arranged in consecutive fashion along the dorsal aspect of the embryo (Fig. 19.1A). The dorsolateral cells of the somite will become the dermomyotomes that will eventually give rise to the skin and the muscle. The ventromedial somite cells will become the sclerotomes; these are precursors of the skeletal system. Around day 35, the sclerotomes condense around the neural tube and the notochord. They will differentiate into a cranial and a caudal half, such that the rostral half of one somite migrates and joins with the caudal half of the somite above to form a vertebral body; this is a process known as resegmentation (Fig. 19.1B). The notochord starts differentiating and vanishing, eventually forming the alar and the apical ligaments at the C1–C2 levels, as well as the nucleus pulposus of the intervertebral disks. Chondrification begins at day 42 when centers appear on both sides of the small remnant of the notochord and coalesce toward the center. Centers also appear

laterally in each vertebral arch and propagate dorsally to form a cartilaginous arch. The chondrification proceeds dorsally to form the spinous process and then proceeds laterally to create the transverse processes. Within its cartilaginous template, ossification begins at day 72 with three primary ossification centers in a typical embryonic vertebra: one in the body and one in each of the vertebral arch halves. Secondary ossification centers start developing in the spine after puberty. There are five centers: one in the spinous process, one in each transverse process, and one ring of epiphysis in the superior and the inferior endplates of the vertebral bodies.

The embryology of the CVJ is unique and complex and deserves special consideration. The subaxial spine (C3–C7) can be considered a unit because each level exhibits the same developmental pattern.

Embryology of the Occipital Condyles

The proatlas is the resegmented sclerotome formed from the combination of the caudal half of the fourth occipital somite and the rostral half of the fifth somite (or first cervical somite). The proatlas forms the condyles, the basion, and the clival tubercle (or third occipital condyle or condylus tertius in some malformations), as well as the apical segment of the dens, and the apical, alar, and transverse ligaments of the dens.¹⁴

Embryology of the Atlas

The C1 resegmented sclerotome comes from the caudal half of the fifth somite (or first cervical somite) and the rostral half of the second cervical somite. The C1 vertebra is mainly formed from the C1 sclerotome: the anterior C1 arch from the hypochordal bow of the C1 sclerotome, and the rest from the lateral portion of the C1 (resegmented) sclerotome. C1 probably does not have contribution from the proatlas. C1 is the only vertebra to develop from only three ossification centers: one in each of its lateral masses and one in the anterior arch. The center in each lateral mass appears around the seventh week of fetal life while the anterior ossification center appears around the end of the first year after birth. Ossification of the posterior arch occurs during the seventh week of intrauterine life. A definitive fusion of the posterior arch of the atlas will only occur between 3 and 5 years of age. Later, between 5 and 9 years of age, the anterior center fuses with the two lateral mass centers.^{15,16}

Embryology of the Axis

The C2 resegmented sclerotome is derived from the caudal half of the sixth somite (or second cervical somite) and the rostral half of the seventh somite (or C3 cervical somite). The dens has contributions from three sclerotomes: the tip arises from the proatlantal sclerotome, the midportion from the first cervical sclerotome, and the base from the second cervical sclerotome. The second cervical sclerotome forms the lower portion of the dens, the centrum, and the dorsal arch of the axis. It has five primary ossification centers: two for the odontoid, two for the lateral masses, and one for the body (Fig. 19.2). The body of C2 fuses with the odontoid process by 3–6 years of age. This fusion line (i.e. subdental or dentocentral synchondrosis), or the remnant of the cartilaginous synchondrosis, can be seen until age 11 years and may be confused with a fracture. A secondary ossification center appears at the apex of the odontoid process (os terminale) between 3 and 6 years of age and fuses by age 12 years (Fig. 19.2).

Embryology of the Subaxial Cervical Spine

The resegmentation process continues throughout the subaxial spine. As stated previously, three ossification sites are present: the body, which arises from a single ossification site, and the two neural arches. The neural arches fuse posteriorly by the age of 2–3 years, and the body

Fig. 19.2: There are five ossification centers in the axis, one within the vertebral body, two in the dens and one in each lateral mass/neural arch. The secondary ossification center forms at the tip of the dens around ages 6–8 and fuses with the dens around age 12. The dentocentral synchondrosis fuses by 3–6 years of life, but is still visible until 11 years of age and can be misinterpreted as a fracture.

fuses with the neural arches between 3 and 6 years of age. Additionally, secondary ossification centers may be seen at the tips of the transverse processes and the spinous processes that may persist until early in the third decade of life and simulate fractures. Secondary ossification centers can also appear at the superior and the inferior aspects of the cervical vertebral bodies and remain unfused until early adulthood.

■ CRANIOVERTEBRAL JUNCTION ABNORMALITIES

There are many developmental abnormalities that can occur at the CVJ. We refer the reader to the excellent detailed manuscript by Pang and Thompson.¹³ In general, these abnormalities can result in deformity, neural compression (of the cervicomedullary spinal cord and the lower cranial nerves) and vascular compromise, and can manifest with abnormal cerebrospinal fluid dynamics (e.g. hindbrain herniation or Chiari I malformations and syringohydromyelia). In a recent review of his extensive personal experience with children afflicted by craniovertebral anomalies, Menezes found that 80% had spastic quadriparesis, 30% had lower cranial nerve palsies, 40% had vertebrobasilar dysfunction, and 30–40% had hindbrain herniation.¹⁷ Hosalkar et al.¹⁸ evaluated 68 patients with 234 osseous upper cervical spine anomalies treated during a 15-year period. In 21 patients, the anomalies were associated with a syndrome and 79% of patients had three or more anomalies. Neck pain was present in 38% of patients; neurologic changes were present in 30%. Forty four (65%) patients eventually required decompression and fusion of the occipitocervical junction.

Malformations of the Occipital Condyles

Duplications or irregular development of the occipital condyles are rare but have been reported.¹⁹ Condylar hyperplasia can be unilateral (i.e. “coconut” condyle) or bilateral and can result in a head tilt and cause myelopathy (Figs. 19.3A to D).^{20,21} Conversely, hypoplastic condyles are underdeveloped and have a flattened appearance and can lead to cranial settling and basilar invagination. A benign third condyle (or condylus occipitalis) has sometimes been discovered in the midline on autopsy.²² This third condyle is a small bony hunch on the anterior rim of the foramen magnum that articulates with the top of the dens or anterior arch of atlas. It is thought to represent a persistent hypochordal bow of the proatlas. A paracondylar process is

a bony exostosis that arises from the skull base just lateral to the occipital condyle and extends inferiorly toward the transverse process of the atlas. It usually has little or no clinical significance, or can be a source of occipitocervical pain that resolves with resection.^{23–26} Browd et al. have demonstrated that patients with Down’s syndrome and congenital occipitocervical instability fail to develop the curved architecture in the occipital condyle that occurs in age-matched controls over time (*see below*).^{27–29}

Occipitalization of the Atlas

Occipitalization—or assimilation of the atlas—occurs in approximately 0.25% of the population. It is characterized by fusion of the occiput to C1 and is generally defined as a failure of segmentation between the fourth occipital and the first cervical sclerotomes.^{30,31} The fusion can be complete, partial, unilateral, and either bony or fibrous (Fig. 19.4).³² Occipitalization of the atlas can occur with various syndromes, including achondroplasia, spondyloepiphyseal dysplasia (SED), Larsen’s syndrome, and Morquio’s syndrome. As such, it usually occurs in conjunction with other anomalies, such as congenital fusion of the second and third cervical vertebrae, basilar invagination, Chiari I malformation, and KFS, although it can be an isolated event.^{33,34} This anomaly is also associated with a high prevalence of anomalous vertebral artery position, which must be reviewed in detail before any surgery is undertaken. In fact, the frequency of vertebral artery anomalies at its extraosseous and intraosseous regions is increased in any patient having osseous anomalies at the CVJ. Tubbs et al.³⁵ found that there was an anomalous osseous pathway as the vertebral artery enters into the cranium in 80% of cadavers in which the posterior atlantal arch or hemiarch was fused to the occiput. A similar observation was reported by Yamazaki et al.³⁶ Abnormal courses of the vertebral artery at the extraosseous region were detected in 10 cases (two had fenestration and eight had a persistent first intersegmental artery), all of which occurred in their group of patients with atlantoaxial subluxation in conjunction with either an os odontoideum or occipitalization of the atlas. Also, 51.9% of these patients (14 out of 31) had a high-riding vertebral artery.

In most cases, the atlas and occiput are fused anteriorly with hypoplastic or anomalous posterior atlantal elements.^{30,37} Many of the afflicted patients are symptomatic, likely because of C1–C2 instability due to a weakened or absent transverse atlantal ligament from undue stresses and abnormal C1–C2 joint configurations.^{36,38,39}

Figs. 19.3A to D: Hyperplastic unilateral occipital condyle (i.e. “coconut condyle”) with platybasia. A 14-year-old male was referred to clinic with a slowly progressive myelopathy. The sagittal (A) and axial (B) magnetic resonance imaging show platybasia, tonsillar herniation and compression of the cervicomedullary junction. The coronal (C) and axial (D) computed tomography reveal a markedly enlarged and abnormal atlanto-occipital joint with what appears to be two separate joint surfaces (*).

Fig. 19.4: An illustration showing a coronal and sagittal view of occipitalization of the atlas. The occipital condyles (“C”) are fused with the lateral masses of the atlas. The anterior (“A”) and posterior (“P”) arches of the atlas are fused with the basion and opisthion, respectively. “O” refers to the odontoid process.

Gholive et al.⁴⁰ recently provided a detailed radiographic and clinical analysis of 30 patients with occipitalization of the atlas. They categorized patients based on where along the atlas the fusion occurred, breaking down the locations of the fusions into three zones. Zone 1 assimilation involves the anterior atlantal arch in front of the lateral masses (20% in their series); zone 2 primarily involves the lateral processes (17%); and zone 3 is fusion at the posterior atlantal arch (13%). Fusions were relatively equally divided among zones, but those with fusions in the lateral masses had the highest prevalence of spinal stenosis (63%). Seventeen patients (57%) had atlantoaxial instability, which is related to the transferred stress (especially, flexion–extension) on the C1–C2 joint by the fusion of the occiput to C1.

The atlantoaxial segment can sustain a “double hit,” if there is also congenital fusion of the C2–C3 segment, which is not infrequent in these patients and was found in over half of Gholve et al.’s patients.^{17,40} These stresses can lead to a reducible form of basilar invagination. Because pannus (granulation tissue) can develop around the odontoid process as the body’s response to limit movement, the lesion becomes irreducible as the patient ages.^{17,41}

Neurologic symptoms in patients with occipitalization of the atlas include weakness, numbness or pain in the upper extremities, and associated upper motor neuron signs, including hyperreflexia and spasticity. Clinically, patients may present with a low hairline, restricted neck movements, and a short neck, all of which are also associated with KFS (*see below*).^{33,42}

Several treatment options are available for occipitalization of the atlas. If the anterior arch of C1 is fused to the occiput without associated translation of C1 relative to C2 (which may indicate an incompetent transverse ligament), the posterior elements of C1 can be resected. Associated atlanto-occipital or atlantoaxial instability should be treated with internal fixation and fusion. In some cases, the atlantoaxial subluxation or basilar invagination can be reduced by the use of traction and cervical extension. If the abnormality is reducible, posterior stabilization alone is adequate.^{43,44} If the spinal cord compression is inadequately reduced, ventral decompression with fusion and stabilization is required.⁴⁵

Atlantal Anomalies

Various congenital anomalies affecting the atlas have been reported either in isolation, with other anomalies, or as part of a syndrome. Absence of the anterior arch is an extremely rare anomaly and is thought to be due to aplasia of the hypochordal bow of the C1 sclerotome.^{46–48} Complete aplasia of the posterior arch of C1 and fusion of the C1 arch to the C2 have also been reported.^{49,50} Recently, an extremely rare case of unilateral enlargement of an atlas facet resulting in cord compression and progressive quadriplegia has been described.⁵¹

Various defects of the posterior ring of C1 have been described.^{52,53} According to the classification of Currarino et al.,⁵² there are five types of anomalies (Fig. 19.5): Type A defects are defined as failure of the two hemiarches to fuse at the posterior midline (i.e. failure of the two lateral ossification centers to unite posteriorly in the midline); Type B, unilateral clefts, ranging from a small defect to a complete absence of one hemiarch; Type C, bilateral clefts

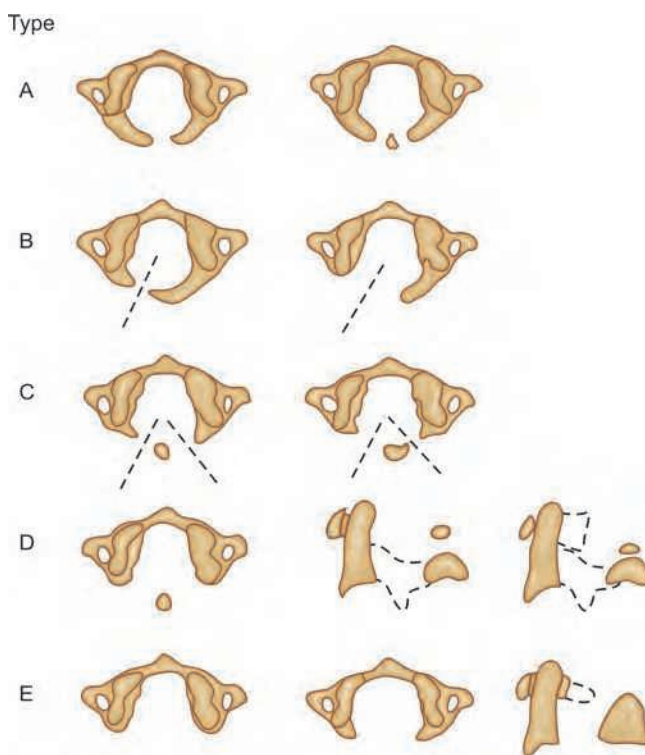

Fig. 19.5: The five different types of posterior atlantal arch defects, as defined by Currarino et al.⁵² Type A: Failure of posterior midline fusion of the two hemiarches. Type B: Unilateral cleft. Type C: Bilateral cleft. Type D: Absence of posterior arch with present posterior tubercle. Type E: Absence of posterior arch and posterior tubercle.

of the lateral aspects associated with preservation of the most dorsal portion of the arch; Type D, the complete absence of the posterior arch with a persistent posterior tubercle; and Type E, the complete absence of the posterior arch and posterior tubercle.

Posterior anomalies are much more common than anterior anomalies. Over a period of 1 year, Senoglu et al. found 40 cases of posterior atlantal arch anomalies in 1,354 evaluated cases (2.95%), whereas they found only one anterior arch defect in 1,104 computed tomography (CT)-documented cases (0.1%).⁵⁴ Evaluation using CT is important because anterior or posterior ring anomalies can often be mistaken for fractures on plain film.^{2,55} These anomalies alone are usually without any clinical consequence, although they are sometimes associated with other anomalies or may themselves cause myelopathy.^{48,56–58}

Atlantal hemirings can cause craniocervical instability that can worsen with time. This anomaly may cause, alone or in combination, disruption of the condylar-C1 articulation and its associated capsular ligaments, disruption

Figs. 19.6A and B: Sagittal computed tomography (A) and magnetic resonance imaging (B) demonstrating basilar invagination, with the tip of the odontoid above the plane of the foramen magnum. This patient also has platybasia. This is defined by drawing a line from the nasion (N) to the tuberculum (T) and from the tuberculum to the basion (B). An angle $>130^\circ$ confirms platybasia.

of the C1–C2 joint, and possibly lack of transverse ligament integrity. As the child grows, the hemirings can migrate or “spread” laterally, leading to progressive deformity, pain, basilar invagination, and myelopathy. Brockmeyer et al.⁵⁹ reported 19 patients with hemirings with a mean age of 22 months at presentation. The mean subluxation between the occiput and C2 on flexion–extension films was 9 mm (range 2–20 mm). Ultimately, 13 patients underwent occipitocervical fusion, and surgery was recommended for four of the remaining six children.

Congenital partial aplasia of the posterior arch of the atlas is a well-described phenomenon in which a bony defect of the posterior arch of C1 is replaced with a dense fibrous band that is mobile and can repeatedly traumatize the posterior spinal cord.^{60–63} Hypoplasia or incurving of the posterior arch, which effectively decreases the space available for the spinal cord, can cause progressive myelopathy.^{64–67} Interestingly, many patients will not present until well into adulthood.^{68–73} Treatment consists of removing the posterior arch.

The arcuate foramen (also known as ponticulus posticus [which means “little posterior bridge” in Latin], foramen arcuale, and foramen atlantoideum posterius) is an anomalous ossification of the posterolateral surface of the atlas that creates a complete or incomplete bone encirclement of the V3 segment of the vertebral artery as it exits the transverse foramen of the atlas. It also houses the vertebral venous plexus and the suboccipital nerve.⁷⁴ It is present in 5–19.3% of individuals and the incomplete type is more common.⁷⁵ This anomaly is usually of no

importance except in patients who need instrumentation of C1, in particular, lateral mass screws. In these patients, identification of this anomaly is important to prevent vertebral injury during placement of the screws.⁷⁶

Basilar Invagination

Basilar invagination, or cranial settling, is characterized by the encroachment of the foramen magnum by the odontoid process resulting in impaction of the cervicomedullary junction (Figs. 19.6A and B). Primary or true congenital basilar invagination is frequently associated with other abnormalities, including atlanto-occipital fusion, hypoplasia of the atlas, hemirings of C1 with “spreading” of the lateral masses, Chiari I malformations, odontoid abnormalities, KFS, and achondroplasia.⁷⁷ Condylar hypoplasia elevates the position of C1 and C2 and often leads to basilar invagination. Acquired basilar invagination, or basilar impression, is caused by softening of the bone at the base of the skull due to osteoarthritis, Paget’s disease of bone, hereditary disorders of connective tissue (such as osteogenesis imperfecta and Ehlers–Danlos syndrome), Hurler’s syndrome, rheumatoid arthritis, tumors or infection.^{78,79}

Generally, basilar invagination can be defined by the amount of protrusion of the odontoid process through the foramen magnum. Although its diagnosis traditionally involved measuring various lines (e.g. Chamberlain’s, McRae’s or McGregor’s lines) or positions of bony landmarks relative to others (e.g. Clark’s method, vertical atlantoaxial index) from lateral radiographs of the cervical

spine, today these measurements are more of historical rather than clinical value.^{30,80} Overlying skull base structures may obscure the identification of the key anatomic structures needed to determine these various measurements and Riew et al.⁸¹ have demonstrated that no one method has high enough sensitivity or specificity for screening purposes. Sagittal CT and magnetic resonance imaging (MRI) are the most informative images to diagnose and determine the degree of basilar invagination.

Pang and Thompson describe three types of congenital basilar invagination.¹³ The first type, anterior basilar impression, results in platybasia in which the nasion-tuberculum-basion angle is increased and the sphenoclival block is severely flattened. This flattening causes the basion to move cephalad and the foramen magnum to be tilted in a lordotic fashion. Along with platybasia, the clivus is shortened and the dens is retroflexed and lordotic. In posterior basilar impression, the second type of basilar invagination, the dens elevates into the cranial cavity either through elevation of the occipital condyles and opisthion or as a result of hypoplastic, flat condyles. The opisthion often invaginates into the foramen magnum. Finally, the third type is the combined form in which basilar impression results from a retroflexed dens and posterior invagination of the opisthion.

Traction is generally used for the initial treatment of basilar invagination to reduce the compression of the neural structures by the odontoid. A posterior occipitocervical stabilization procedure can be performed to maintain the reduction. If the invagination cannot be reduced, a transoral decompression, followed by a posterior occipitocervical fusion, may be required.^{78,82-84} Patients with an associated Chiari malformation type 1 or 1.5 and syringomyelia require foramen magnum decompression with duraplasty in addition to dorsal craniocervical junction fusion.^{45,77,82} For those patients without a concomitant Chiari malformation, Goel suggests that the treatment should be directed at distracting and fixating the atlanto-axial joint that will thus reduce the basilar invagination.⁸⁵

Axis Anomalies

Although they are less common than defects of C1, posterior C2 arch defects are often more problematic because they must be differentiated from traumatic spondylolisthesis and persistent neurocentral synchondrosis.^{86,87} Defects are generally characterized by sclerosis of the fragments that separate on flexion and malformation or underdevelopment of the posterior arch of C2.⁸⁸ Trivedi et al.⁸⁹

reported a case in which the patient had complete absence of the posterior elements of C2 and excessive motion between C2 and C3. The patient was treated with an occiput to C3 fusion. Spondylolysis of C2 is a rare diagnosis. It is described as a smooth and well-corticated defect or cleft between the C2 pedicles and the vertebral body. In contrast to subaxial spondylolysis described below, patients are usually younger; the vast majority are asymptomatic and less likely to have instability at C2–C3.⁹⁰

Dysplastic or hypoplastic posterior arches of C2 may cause myelopathy. The clinical and radiographic picture is similar to that of hypoplastic posterior arch of C1 in that the arch is often bifid and invaginating into the spinal canal and many patients present in adulthood. They, in fact, may be found in combination with atlantal anomalies.⁹¹ Treatment typically entails performing a laminectomy and fusion, if there is abnormal motion.⁹²⁻⁹⁴

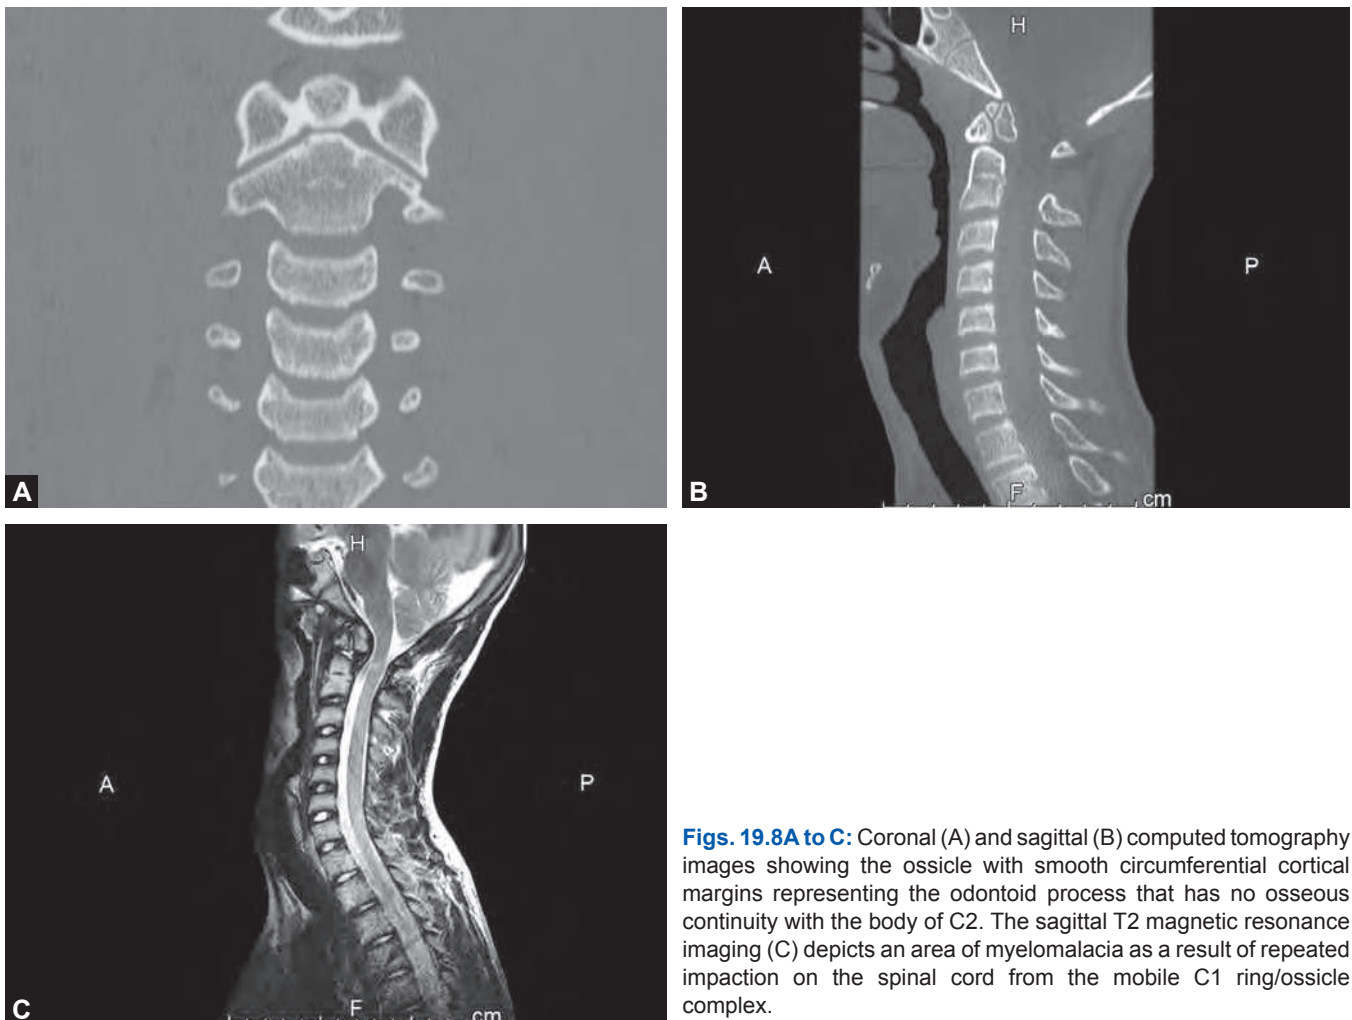

Anomalies of the Dens

There are a number of congenital abnormalities of the dens, primarily disordered formation, but also involving abnormalities of shape, which may result in atlanto-axial instability or compression of neurologic structures. Aplasia (agenesis) or hypoplasia of the dens is rare and usually found in syndromic patients (e.g. spondyloepiphyseal, Morquio's, Hurler's syndrome)⁹⁵; both aplasia and hypoplasia result in instability and require stabilization.⁹⁶ On the contrary, agenesis of the apical portion of the dens yields a shortened dens but does not cause instability. The odontoid may also be misshapen, angled posteriorly (retroflexed) in particular causing ventral brainstem compression and be associated with hindbrain herniation, as discussed previously (Figs. 19.7A and B). Tubbs et al.⁹⁷ found that a retroflexed odontoid was associated with syringomyelia; particularly, holocord syringes and higher grades of angulation were more common in female patients and with a greater degree of caudal displacement of the fourth ventricular obex. Transoral or transnasal resection of the retroflexed dens is required followed by posterior stabilization.⁹⁸⁻¹⁰⁰ A completely bifid or duplicate odontoid is exceedingly rare,¹⁰¹ in contrast to a dens bicornis in which only the tip is bifid and is of no clinical consequence.

Os odontoideum is a dissociation between the body of C2 and the dens, such that a disconnected ossicle takes the place of an intact odontoid process (Figs. 19.8A to C). The debate regarding the etiology of an os odontoideum continues with most feeling that there are both traumatic

Figs. 19.7A and B: (A) T2 Sagittal magnetic resonance imaging (MRI) showing a retroflexed odontoid, Chiari malformation and an associated syrinx. (B) MRI 6 months after suboccipital craniectomy and duraplasty with re-establishment of cerebrospinal fluid at the cervicomedullary junction and a smaller syrinx.

Figs. 19.8A to C: Coronal (A) and sagittal (B) computed tomography images showing the ossicle with smooth circumferential cortical margins representing the odontoid process that has no osseous continuity with the body of C2. The sagittal T2 magnetic resonance imaging (C) depicts an area of myelomalacia as a result of repeated impaction on the spinal cord from the mobile C1 ring/ossicle complex.

and congenital types.¹⁰²⁻¹⁰⁵ Furthermore, os odontoideum has been found in twins¹⁰⁶ and families,^{107,108} further strengthening the theory of a congenital etiology. Based on the position of the dens tip, two types of os odontoideum are described: orthotopic and dystopic. In the orthotopic type, the dens fragment lies in anatomic position and moves with the arch of C1. In dystopic os odontoideum, otherwise known as os avis, the ossicle is near or fused to the basion (clivus). The orthotopic type is much more common.

Dynamic imaging with flexion/extension films should be obtained to identify any instability and an MRI should be obtained to evaluate the spinal cord. The treatment of an unstable os odontoideum is a C1–C2 fusion.¹⁰⁹⁻¹¹¹ However, controversy exists with the management of a patient with an incidental or asymptomatic os odontoideum without radiographic instability. Some authors—including ourselves—have argued that even under these circumstances, virtually all patients should be offered fixation and fusion as the presence of an os odontoideum inherently creates an unstable atlantoaxial segment and places the patient at risk for a potentially catastrophic spinal cord injury with even minor trauma.¹¹²

It is important to differentiate an os odontoideum from an ossiculum terminale persistens. In the latter, the tip of the dens, the ossiculum terminale, fails to fuse with the remainder of the dens. The ossiculum terminale is usually much smaller than an os odontoideum and is firmly bound to the main body of the dens by cartilage. The ossicle lies at the level of the atlantal ring above the transverse atlantal ligament. Consequently, it is seldom the source of instability.

SUBAXIAL SPINE ABNORMALITIES

Anomalies of the subaxial cervical spine also occur but overall are less common than those found in the craniocervical junction. They can broadly be classified as disorders of either formation or segmentation and can be found in isolation or in combination with other spinal anomalies. Examples include midline vertebral body clefts, sagittal and coronal hemivertebrae, hypoplasia or complete absence of a vertebra, absence or malposition of a pedicle, hypertrophy of a lamina or spinous process, and block (or fused) vertebrae (most commonly found between C2 and C3).^{100,113-123} Radiographic characteristics typical of a congenitally absent cervical pedicle, which are almost always unilateral, are an enlarged ipsilateral neural foramen because of the absent pedicle; a dysplastic, dorsally

displaced ipsilateral articular pillar and lamina; and a dysplastic ipsilateral transverse process. Other osseous abnormalities are frequently associated with an absent pedicle and include spina bifida occulta, vertebral body or arch fusion, and additional hypoplastic pedicles.

Cervical spondylolysis, which is a cleft between the superior and inferior articular facets of the articular pillar or lateral mass (it is the cervical equivalent of the pars interarticularis of the lumbar spine), is a rare congenital spinal anomaly.¹²⁴⁻¹²⁷ Characteristic radiographic findings include well-corticated margins at the defect, a characteristic “bow tie” deformity, and ipsilateral dysplastic facets. Compensatory hypertrophic changes of the adjacent articular processes, spina bifida, and spondylolisthesis are frequently seen.¹²⁸ The spondylotic cleft and spondylolisthesis give the appearance of posterior displacement of the dorsal pillar. Cervical spondylolysis most commonly occurs at a single level (the most common level is C6) with bilateral clefts, but multilevel and unilateral cases have been reported.^{124,125,129-132} This anomaly is typically discovered in adulthood and can present from asymptomatic to mild nonspecific neck pain and stiffness or radiculopathy but myelopathy unusual. Surgery is considered when there is excess motion or subluxation.

SYNDROMES

Numerous syndromes have cervical anomalies among their key features. We will briefly discuss the more common ones. More detailed descriptions can be found in several recent review articles.^{133,134}

Klippel-Feil Syndrome

In 1912, Klippel and Feil reported the case of a patient with the triad of a short neck, low hairline, and limited neck mobility who was found to have only 12 discernible vertebrae on autopsy.¹³⁵ Klippel-Feil syndrome refers to any congenital fusion of the cervical spine of two or more cervical vertebrae, with the most common level being C2–C3 (Figs. 19.9A and B).¹³⁶ Despite the initial description, it is now recognized that fewer than 50% of patients with congenital fusion of the cervical spine will have the triad of classic characteristics.¹⁰ Torticollis, or neck webbing, is seen in only 20% of patients with KFS.¹³⁷⁻¹⁴⁰ Facial asymmetry may be associated with cervical spine anomalies and hearing loss can be present in up to 30% of patients with KFS.¹³⁹⁻¹⁴¹ Other associated syndromes include Wildervanck's, Rokitansky-Kuster-Hauser, or Goldenhar's syndromes.

Figs. 19.9A and B: (A) Cervical spine X-ray of a 20-year-old male with Klippel-Feil syndrome demonstrating Sprengel deformity, fusion of the anterior and posterior elements of C2-C3 and an isolated posterior tubercle of C1. (B) The MRI gives a clearer picture of the segmentation defects, the ossiculum terminale C3 and absence of the anterior C1 arch, and a thin cervical spinal cord surrounded by a large CSF space.

Other cervical abnormalities found in KFS include occipitalization of the atlas, basilar invagination, hemivertebrae, and scoliosis. Scoliosis, which occurs in up to 60% of KFS patients, is more likely in patients with fusion of the mid and the lower cervical spine region, multiple contiguous congenitally fused segments, and associated vertebral malformations (e.g. hemivertebrae).¹⁴² Risk factors for basilar invagination (i.e. an odontoid tip >4.5 mm above McGregor's line) include four or more segments that are fused, female sex, and coronal angulation (e.g. scoliosis) $>10^\circ$.¹⁴³ However, 4.5 mm or greater migration of the odontoid was not synonymous and the presence of symptoms was not statistically correlated with the amount of odontoid migration.

Numerous musculoskeletal anomalies are associated with KFS, the most common being scoliosis (usually congenital), which occurs in up to 60% of patients. Sprengel's deformity, a congenital elevation of the scapula, can be seen in 20–35% of patients with KFS. An osseous, cartilaginous or fibrous connection between the scapula and the lower cervical spine is present about 50% of the time. Recently, Mooney et al.¹⁴⁴ described an osseous structure extending from the medial scapula to the clavicle and occipital region of the skull associated with a Sprengel's deformity. The Sprengel's deformity is thought to arise from failure of descent of the scapula from the first embryologic cervical level to its normal position, just caudal to the first rib.¹⁴⁵ Other musculoskeletal anomalies include cervical

ribs, rib anomalies, and hemivertebrae. Cardiovascular abnormalities are reported to occur in up to 14% of patients with KFS. Genitourinary abnormalities are also associated with KFS, affecting up to 64% of patients with the most common manifestation being unilateral renal agenesis.^{138,146,147} Abnormalities noted in the renal system may point to abnormalities of the reproductive system, particularly in females.

The most common clinical presentation of KFS is limited range of motion, particularly lateral bending. However, if fewer than three cervical vertebrae are fused, motion of the cervical spine may appear normal because adjacent levels may compensate. Thus, patients with more extensive neck fusions may present at an earlier age. Similarly, higher fusions near the CVJ often present earlier with pain, whereas those with lower cervical fusion present later when symptomatic junctional degeneration develops.¹⁴⁸ Samartzis et al.¹⁴⁹ have shown that involved segments between C2 and T1 often become completely fused (demonstrating bridging bone both anteriorly and posteriorly) as children age. Conversely, the upper cervical segments do not show such a pattern. Instead, fusion of the posterior elements was more common than fusion of the anterior elements. The same authors also found that congenital fusion may arrest the normal vertebral development as these levels tended to have greater canal dimensions (i.e. space available for the cord) and the cephalad-to-caudal dimension of the vertebral bodies was less.¹⁵⁰

Neurologic disturbances associated with KFS include developmental abnormalities of the central nervous system (such as brainstem malformations), myelopathy as a result of long-standing spinal cord compression, radiculopathy as a result of nerve root irritation, and nonspecific symptoms of headache, weakness, and numbness. Up to 20% of patients with KFS will exhibit synkinesis in which involuntary mirrored motions, primarily in the upper extremities, are observed.^{151,152} The cause is unknown, but autopsy results of two patients with KFS and synkinesia showed an incomplete pyramidal decussation. Synkinesia is generally effectively treated with occupational therapy, and the condition often subsides as the patient ages.

Routine plain radiography can quickly identify an obvious congenital fusion or cervical stenosis. Flexion and extension views provide a dynamic snapshot to identify instability of the atlanto-occipital, atlantoaxial, and subaxial joints, although radiography of the cartilaginous spine of children younger than 8 years of age can be difficult to interpret. Magnetic resonance imaging should be used in the setting of suspected compromise of the brainstem or the spinal cord and to detect other central nervous system lesions, such as syringomyelia, tethered cord, diastematomyelia, and Chiari malformation.^{10,153} Further imaging of the thoracic and lumbar spine is warranted in patients with KFS to identify abnormalities in these regions.¹²

Because many patients are asymptomatic throughout life, treatment for KFS must be individualized. For patients with atlanto-occipital instability, occipitocervical fusion should be performed.⁴³ Atlantoaxial instability is best approached with C1–C2 transarticular screw fixation techniques. Patients with subaxial instability typically will not present with neurological symptoms but may have significant degenerative disc disease. Subaxial fusions may place additional strain on the adjacent motion segment leading to premature disc degeneration. These patients may be successfully treated with discectomy and fusion. Symptomatic cervical stenosis over multiple levels is generally treated with posterior decompression and fusion.^{154,155}

Down's Syndrome

Down's syndrome, or trisomy 21, is the most common inherited chromosomal disorder in humans. The craniovertebral joints may be unstable in these patients for a variety of reasons (Figs. 19.10A to D). Lack of a concave C1 superior articulating surface in conjunction with a

failure to develop the curved architecture in the occipital condyle results in a flat or "rocker bottom" joint.^{27,28} Down's syndrome patients frequently have atlantoaxial joint instability as a result of a lax transverse ligament, the presence of an os odontoideum, or odontoid hypoplasia.¹⁰⁹ This instability has been a source of controversy relating to the participation of Down's syndrome patients in the Special Olympics. Since the early 1980s, the Special Olympics Inc. has defined atlantoaxial instability as an atlantodental interval (ADI) >4.5 mm. Any instability automatically disqualifies children from participating in the high-risk activities. However, this restriction can be waived if an acknowledgment of the risks is signed by an adult athlete; if the athlete is a minor, his/her parent or guardian signs this acknowledgment and two physicians must give written certification. These restrictions remain controversial since there has never been a reported case of an asymptomatic patient with atlantoaxial instability developing neurologic injury due to a sports-related injury.^{156,157} Pizzutillo and Herman proposed that patients with an ADI <4.5 mm can continue with unrestricted activity; those between 4.5 and 10 mm are at risk and should be kept from high-risk activity; those with an ADI >10 mm or any symptomatic patient with cord signal changes indicative of spinal cord injury should be fused.¹⁵⁸

Achondroplasia

Achondroplasia has a significant association with craniocervical deformities. A narrowed foramen magnum and upper cervical stenosis may be seen with CT and MRI in a majority of patients (Figs. 19.11A and B).^{159,160} Compression may result from hypertrophied margin of the foramen magnum, anterior extension of the squamous portion of the occipital bone into the foramen magnum, abnormal fusion of the posterior neural arch of the atlas with the posterior margin of the foramen magnum, or dense fibrotic epidural bands commonly found anterior to the posterior ring of the atlas. There has also been a case report of overgrowth of the opisthion into the foramen magnum.¹⁶¹ In patients with achondroplasia, the odontoid process often projects posteriorly and superiorly into the small foramen magnum, resulting in medullary compression.¹⁶²

Although foramen magnum stenosis is a common radiologic finding in pediatric achondroplasia patients, only a fraction of those patients will exhibit symptoms of cervicomedullary compression. For this reason, treatment decisions should be based on signs or symptoms of neurological dysfunction rather than on the radiological

Figs. 19.10A to D: This 3-year-old child with Down's syndrome had screening X-rays done prior to enrolling in a physical recreation program. Neutral (A), flexion (B) and extension (C) plain films demonstrate 8–9 mm of motion between the occiput and C1 and 3–4 mm widening of the atlantodental interval (ADI). (D) The child underwent an occipitocervical fusion.

evaluation alone. Treatment involves suboccipital decompression usually without duraplasty to accommodate the lower brainstem and upper spinal cord and is very successful at improving or completely resolving preoperative neurologic symptoms.¹⁶³ Duraplasty is often avoided because it is difficult to achieve a water-tight closure and many children have underlying hydrocephalus secondary venous hypertension from jugular foramen stenosis.¹⁶³

Larsen's Syndrome

The triad of distinctive facial features, dislocations of multiple joints, and spinal anomalies was first described by Larsen in 1950 in a series of his patients.¹⁶⁴ The spinal manifestations include scoliosis, spinal stenosis, abnormal

segmentation, neural arch defects, coronal cleft vertebrae, hemivertebrae, and anteroposterior dissociation. Dramatic midcervical multilevel kyphosis is often present and can lead to instability, progressive myelopathy, weakness, and even sudden death in Larsen's syndrome.¹⁶⁵⁻¹⁶⁷ For this reason, the cervical spine should be imaged immediately after a diagnosis of Larsen's syndrome has been made.

Goldenhar's Syndrome

Goldenhar's syndrome, also known as oculoauriculovertebral dysplasia, is a clinically diverse disorder characterized by hemifacial microsomia, epibulbar dermoid appendages, and spinal defects. Segmentation defects (i.e. block vertebrae) are common in the cervical spine, whereas

Figs. 19.11A and B: Images from an 8-year-old achondroplastic dwarf. (A) T1 Sagittal image shows severe stenosis of the foramen magnum along with hypoplasia of the dens and clivus. (B) The computed tomography confirms the narrowed foramen magnum with an ovoid rather than circular shaped foramen magnum, typical of achondroplastic patients.

formation defects (i.e. hemivertebrae) are more common in the thoracic spine, leading to scoliosis. Other anomalies include basilar invagination, retroflexed odontoid, assimilation of the atlas, and odontoid hypoplasia leading to atlantoaxial instability.^{168,169}

Spondyloepiphyseal Dysplasia

Spondyloepiphyseal dysplasia encompasses several disorders characterized by abnormal growth of the spinal vertebrae and epiphysis. Atlantoaxial instability, as a result of odontoid hypoplasia, and os odontoideum or transverse ligament laxity, is the most common spinal manifestation of SED in children.¹⁷⁰ In addition, the ring of C1 is small, which further compromises the sagittal canal diameter at this level.

Morquio's Syndrome

Mucopolysaccharidosis type IV (MPS IV), or Morquio's syndrome, is an autosomal recessive lysosomal storage disease characterized by an inability to metabolize keratan sulfate, a glycosaminoglycan found predominantly in cartilage and in the cornea. As in SED, the most common cervical manifestation is atlantoaxial instability due to odontoid dysplasia (hypoplasia, aplasia, os odontoideum) or ligamentous laxity.^{171,172}

Congenital Multilevel Cervical Disconnection Syndrome

Congenital multilevel cervical disconnection syndrome is a newly described syndrome in which there is an osseous disconnection between the anterior and posterior elements resulting in a severe kyphotic deformity and myelopathy, similar to what is found in Larsen's syndrome (see Fig. 19.4).¹⁷³ Patients require extensive anterior and posterior reduction, decompression, reconstruction, and stabilization/fusion procedures. The pathology is thought to be due to failure of chondrification centers in the centrum and dorsal arches to coalesce.

SUMMARY

Congenital anomalies of the cervical spine vary widely. Patients may present with abnormalities as simple as two congenitally fused vertebrae requiring no treatment, or as complex as craniocervical instability requiring occipito-cervical fusion. It is important to recognize that some of these malformations may be associated with other defects involving the cardiovascular, neurological, renal, and reproductive systems. The true incidence of these anomalies is not known for certain, partly because of their frequent asymptomatic nature. Recognizing those congenital abnormalities that can contribute to an unstable cervical spine or critical spinal stenosis may prevent a catastrophic spinal cord injury.

KEY POINTS

- Understanding the embryology of the cervical spine helps us to understand the development and progression of these anomalies.
- Congenital cervical anomalies can occur in isolation or in association with a syndrome.
- Congenital cervical anomalies can be asymptomatic or cause significant neurologic deficits.
- The true incidence of congenital cervical anomalies is likely largely unreported and difficult to quantify due to many asymptomatic patients.
- Craniocervical junction anomalies are more common and frequently require surgical stabilization.

ACKNOWLEDGMENT

We thank Andrew J Gienapp for proof reading this manuscript.

- The embryology of the bony craniovertebral junction (CVJ) is reviewed with the purpose of explaining the genesis and unusual configurations of the numerous congenital malformations in this region. Representative examples of the main constituents of this classification scheme are given, and their surgical treatments are selectively discussed.
- Browd SR, McIntyre JS, Brockmeyer D. Failed age-dependent maturation of the occipital condyle in patients with congenital occipitoatlantal instability and Down syndrome: a preliminary analysis. *J Neurosurg Pediatrics*. 2008;2:359-64.

The purposes of this study was to establish normative data characterizing the shape of the occipital condyle in healthy children and compare these data with measurements collected in patients with congenital occipitoatlantal instability or Down's syndrome. The effectiveness of CT and plain radiography data were also compared.

- Gholve PA, Hosalkar HS, Ricchetti ET, et al. Occipitalization of the atlas in children. Morphologic classification, associations, and clinical relevance. *J Bone Joint Surg Am*. 2007;89:571-8.

Thirty children with occipitalization were studied with computed tomography and/or magnetic resonance imaging and a description of their clinical characteristics. A new morphologic classification of occipitalization was developed based on four patterns according to the anatomic site of occipitalization (zones 1, 2, and 3 and a combination of those zones), each of which may have different prognosis implication.

- Brockmeyer DL, Brockmeyer MM, Bragg T. Atlantal hemirings and craniocervical instability: identification, clinical characteristics, and management. *J Neurosurg Pediatr*. 2011;8:357-62.

The authors present a series of 19 patients with atlantal hemirings, a disorder resulting in congenital craniovertebral instability. Presentation, treatment, imaging, and follow-up data obtained in patients with atlantal hemirings were assessed to identify factors relevant to craniocervical instability. The authors believe that this anomaly is the underlying cause of progressive instability in a significant proportion of patients with craniocervical abnormalities. The presence of atlantal hemirings should prompt immediate and thorough neurosurgical evaluation.

- McKay SD, Al-Omari A, Tomlinson LA et al. Review of cervical spine anomalies in genetic syndromes. *Spine (Phila Pa 1976)*. 2012;37:E269-77.

The literature was reviewed for cervical spine issues in 10 specific syndromes. The information is presented in the following order: First, the identification and treatment of midcervical kyphosis in Larsen's syndrome and diastrophic dysplasia. Next, the upper cervical abnormalities seen in Down's syndrome, 22q11.2 deletion syndrome, pseudoachondroplasia, Morquio's syndrome, Goldenhar's syndrome, spondyloepiphyseal dysplasia congenita, and Kniest dysplasia. Finally, the chin-on-chest deformity of fibrodysplasia ossificans progressiva.

Congenital Anomalies of the Spinal Cord

INTRODUCTION

Anomalies of the spine and the spinal cord are often collectively termed spinal dysraphisms. The term “spinal dysraphism” encompasses a heterogeneous group of congenital spinal anomalies where the midline structures fail to fuse early in fetal life and other anomalous development of the caudal cell mass. Malformation of spinal cord may occur in isolation or can be associated with anomalies in the bony spine, nerve roots or covering membranes, or viscera as all these structures develop at the same time.¹

The true incidence of spinal dysraphism is still unclear and is probably underestimated. However, there is a decline in incidence in the last two decades due to various factors, which include better nutrition in women, timely supplement of folate, and better prenatal diagnosis of abnormalities. Spinal dysraphism can be classified as closed or open, depending on whether the overlying skin is intact or deficient. The closed form of spina bifida is termed spina bifida occulta, where the defect is well covered with full thickness skin. They are mostly diagnosed incidentally. The open forms that include myelocele, meningocele, and myelomeningocele are often associated with hydrocephalus and Arnold–Chiari malformation type II and may be classified as spina bifida aperta.

EPIDEMIOLOGY

Spina bifida occulta occurs in about 20–30% of the total population. In isolation, it is often an incidental finding and usually of no clinical importance. However, it may occasionally be associated with diastematomyelia, tethered cord, lipoma, or dermoid tumor. In the presence of occult spina bifida, >90% of patients have a tethered cord,^{2,3} approximately 23.7% have a dermal sinus,¹ and caudal regression syndrome accounts for 16.3%.¹ There is usually an overlying cutaneous manifestations including lipoma, hemangioma, cutis aplasia, dermal sinus, or hairy patch.

Open Spinal bifida is a midline congenital defect with a reported incidence of 2–4/1,000 live births.¹ Myelomeningocele accounts for 98.8% of the open spinal dysraphisms.^{4,5} Females are affected slightly more often than males, with the firstborn being usually affected more often. The most common locations for these malformations are, in decreasing frequency, lumbosacral, thoracolumbar, and cervical spine.^{5,6} In the recent years, the true incidence of myelomeningocele has varied geographically from region to region based on their diet, fortification of food with folic acid supplements, education and awareness levels, availability of prenatal diagnosis, and elective termination.^{7–9} Patients with open spinal dysraphism almost always have associated Chiari II malformation. Myelocele is a rare malformation and represents

only 1.2% of all open spinal dysraphisms.⁵ Sacral agenesis occurs in approximately 1 per 7,500 births without a gender predisposition. In the normal adult population, the conus terminates at L2 level in 95% of cases.^{9,10} Tethered cord implies low-lying conus, but tethered cord may occur in the presence of conus in normal position.⁹⁻¹⁵ Up to 15% of patients with repaired myelomeningoceles will experience a secondary tethered cord syndrome (TCS) later in life.¹⁶

PATHOGENESIS

Chapter 17 deals with the normal embryology and development of the spine and the spinal cord. Spinal cord embryological development occurs through *three consecutive periods* gastrulation, neurulation, and caudal regression.^{5,9,10,17-19} The trilaminar embryo composed of endoderm, mesoderm, and ectoderm develops by day 18 of gestation. The mesoderm then releases factors that induce the differentiation of the overlying neuroectoderm forming the neural plate. This stage is called the *gastrulation*. After gastrulation, the ectoderm above the notochord folds to form the neural tube, which gives rise to the brain and the spinal cord, a process known as *neurulation*. The neural folds subsequently fuse starting from the lower medulla rostrally proceeding caudally. The anterior neuropore closes at about 24 days and the posterior neuropore at 26–28 days, *primary neurulation*. The central canal is formed and is lined by ependyma. The caudal end of the neural tube formed by a group of undifferentiated cell mass develops vacuoles. These vacuoles coalesce to meet the central canal and cause elongation of the neural tube in a process called *canalization*. When caudal neuropore fails to close, open dysraphism ensues. From then until day 49 to 56, *secondary neurulation* sets in forming the conus tip and the filum terminale. Defective secondary neurulation results in the distal spinal cord connected with the epidermis by tissues of mesenchymal origin, causing tethering later on in life. The conus medullaris ascends as the spine grows, forming the caudal portion of the neural tube by *caudal regression*. From the coccygeal region during intrauterine development, the conus lies at the L2–L3 level at birth and in almost 100% by 3 months lies at L1–L2 level after full-term gestation.^{5,9,19} The spinal cord terminates at or above the inferior aspect of the L2 vertebral body in 95% of the population and at or above the L1–L2 disc space in 57% of the population. Since a defect occurs so early in pregnancy (Table 20.1), folate supplement, proven to be effective in preventing neural tube defects, has to be given in the anticipation of pregnancy.

Table 20.1: Embryological classifications of spinal dysraphism.

Developmental stage	Abnormality
Gastrulation	Neurenteric cysts and fistula Split cord malformations (diastematomyelia, diplomyelia) Neurenteric remnants Dermoid/epidermoid tumors
Canalization	Dermal sinus Pilonidal sinus Fistulas
Primary neurulation	Meningocele Myelomeningocele Myelocele Lipomyelomeningocele Lipomyeloschisis Intradural spinal lipoma
Secondary neurulation	Tight filum terminale Filum terminale lipoma
Caudal regressive	Intrasacral meningocele Sacral cysts Abnormal filum (hypertrophy, fatty infiltration)

Spinal cord anomalies result from a complex interaction between several genes and poorly understood environmental factors. Some of the risk factors that have been proposed are as follows:

1. Genetic—a family history is the strongest risk factor.^{7,18}
2. Environmental factors—folic acid deficiency; women planning pregnancy must take 0.4 mg of folic acid daily for 3 months before conception and up to 3 months during pregnancy.^{20,21} About 77% of spinal bifida cases can be prevented by this.^{7,18}
3. Medication—Some drugs taken during pregnancy can cause spinal cord anomalies. Sodium valproate and folic acid antagonist, like carbamazepine, phenytoin, phenobarbital, trimethoprim and primidone, have an increased risk.
4. Pregestational diabetes has a risk of developing both brain and spinal cord abnormalities.⁷
5. Obesity.
6. Raised body temperature.

CLINICAL EVALUATION

The clinical evaluation of a patient with a suspected spinal cord anomaly starts with a detailed history followed by clinical examination. The history should include the prenatal factors, birth history, and child's development until presentation. A prenatal history of a sibling or relative

Fig. 20.1: Hairy patch in the back of two children with underlying vertebral segmental anomalies and split cord malformation at the same level.

Fig. 20.2: Arrowhead shows a dermal sinus and the arrow shows a capillary hemangioma in a baby with underlying low-lying tethered cord with a syringomyelia.

Courtesy: Mr John Firth, Nottingham, UK.

with spinal cord abnormalities and other risk factors for developing a spinal cord abnormality discussed previously should be excluded. Birth history to rule out cerebral asphyxia and trauma should be evaluated. Neurological manifestations, such as pain, altered gait, deformity, change in motor and sensory function, and bowel and bladder disturbance, should be discussed.

Physical examination starts with complete visualization of the entire body including the entire spine up to the sacral cleft. Leg length discrepancy, calf muscle thickness on both sides, inequality of feet, varus and valgus

deformities, clawing and clubfoot should be inspected. Cutaneous lesions commonly seen in spinal cord abnormalities are hairy patches (Fig. 20.1), dermal appendages, dimples, capillary hemangiomas (Fig. 20.2), nevi, subcutaneous lipomas, sinus tracts or fistula, and terminal tail (Fig. 20.3). Early scoliosis or kyphoscoliosis is an indication of possible intraspinal abnormalities. Increased frequency of urine and loss of control of bladder and bowel with other associated abnormalities discussed above may suggest intraspinal abnormalities.

Neurological examination of the central and peripheral nervous system should be performed. Delayed walking and balance in sitting or standing in a toddler should raise suspicion of a spinal dysraphism. In older children, an asymmetry of the abdominal reflexes, hyperreflexia, spasticity, mild weakness of a single limb, atrophy, painless ulceration, ataxia, altered gait, and bladder or bowel incontinence may be the only signs sometimes of an underlying intraspinal abnormality.

■ ABNORMALITIES

Lipomyeloschisis

Lipomyeloschisis is defined as a dorsal spinal dysraphism with lipoma. It consists of skin covered focal spina bifida with extension of the subcutaneous lipoma through a dural defect to the central canal of the spinal cord. This involves an extension of the lipoma into the surrounding

subarachnoid space that contains neural tissue, cerebrospinal fluid (CSF), and meninges to form a large meningocele.^{5,6,22} Tethering of the cord is very common at this level (Fig. 20.6). The bony defects that may be present involve the posterior elements of the spine, segmentation anomalies, and sacral dysgenesis. Though several forms have been described, the clinically important forms that cause progressive neurologic dysfunction via tethering are intradural lipoma, lipomyelomeningocele, and fibrolipoma of the filum terminale. Failure to differentiate the three types may lead to inaccurate prediction of prognosis.²³

Intradural Lipoma (Lipoma of the Spinal Cord)

These are fatty accumulations that are completely intradural, and often intramedullary. They are very rare comprising of 4–7% of all spinal lipomas²⁴ and 1% of all spinal cord tumors. In adults, they are found commonly in the thoracic region and tend to be dorsally located and may demonstrate an exophytic component (Figs. 20.4A to D). In children, they arise more commonly in the cervical and cervicothoracic region.^{24,25}

The pathogenesis of these tumors is poorly understood and can be associated with diastematomyelia or vertebral anomalies including spina bifida. They do not have any subcutaneous extension and symptoms are mostly due to either tethering in the lumbosacral region or due to cord compression in the cervical and thoracic region frequently becoming symptomatic in the second and third decade of life. These tumors can remain unchanged for several years but can also grow as part of the normal increase of adipose tissue that occurs throughout childhood, other than in particular conditions, such as obesity or pregnancy.²⁶ Reduction of weight in obese patients will reduce the size of the tumor and may not require surgical treatment.

The common symptoms are pain, dysesthesia in the limbs, motor deficits, wasting, gait difficulties, and incontinence. When patients present with neurological symptoms they tend to deteriorate rapidly and surgery must be considered. The aim of surgery is to achieve tumor mass reduction as the resection margins between the tumor and the spinal cord is usually not clear (Fig. 20.5). Subtotal resection of the tumor usually gives long-lasting excellent results as they are very slow growing.

Lipomyelomeningocele or Lipoma of the Conus Medullaris

These are usually a subcutaneous fatty mass that passes through a midline defect in the lumbodorsal fascia, the vertebral neural arch, and the dura to merge and infiltrate the spinal cord causing tethering.²⁷ They occur in 1 in 4,000 births in the United States and females are more at risk.^{1,5,1,28}

Lipomyelomeningocele arise when disjunction between cutaneous ectoderm and neuroectoderm (neural tube) occur early.²⁴ The open neural tube is exposed to the ingrowth of mesodermal derivative tissues, like adipocytes (fatty mass). The adipocytes in the lumbosacral lipoma are similar to those of the normal adipose tissue except that they lie in a densely adherent fibrous connective tissue stroma. Though several terms are used in the literature to describe the lipomas in this region a classification system incorporating the anatomical features and natural history of the lipomas is used to facilitate a logical treatment approach.²⁹ This helps the surgeon to understand on the location of the neural structures, meningeal covering, and site of tethering in relation to the fatty mass. In the dorsal variant, the lipoma attaches directly to the dorsal conus medullaris and the nerve roots emerge from the ventral and lateral aspects. In the caudal variant, the lipoma from the central canal exits the cord at the filum terminale expanding the conus. The nerve roots are found to transgress the fatty mass, some of which may be nonfunctional. The final transitional variant consists of both variants and nerve roots may pass between the fatty mass and be functional (Fig. 20.7).

The diagnosis in children can often be missed unless there is a presence of cutaneous markers (50%). A nontender mass is seen in about 90% of cases usually lying in the midline. In one third of children it may be seen in a paramedian location and they present with more neurological deficits than midline masses. Asymmetrical abnormalities usually foot length, leg length, and muscle mass discrepancies are seen. Children usually presenting between 3 and 6 years of age have neurological defects at presentation compared with children who present younger.^{30,31} Bladder dysfunction presents as repeated urinary tract infections, altered or delayed voiding, or frank incontinence.²⁴ The older the child presents with urinary dysfunction the more irreversible the outcome

even with surgery. Adults usually present with back pain or neurological deficits including bladder symptoms. Pain is generalized or radicular and can be precipitated by physical activity or trauma. The clinical features are usually due to the tethering effect produced by the lipomyelomeningocele and may be either due to the direct mechanical tension causing neurological deficits³² or due to ischemic injury from tethering.^{32,33}

In patients presenting with clinical deficits the decision is straightforward. In those who do not have a detectable neurological symptom or deficit there is no consensus regarding prophylactic surgery. Though prophylactic surgery for asymptomatic congenital spinal lipomas remains controversial there is growing evidence in favor of surgery, which offers longer progression free survival. The argument offered against prophylactic surgery is that it does not prevent late neurological deficits irrespective of surgery intervention.³¹ The goals of surgery are to release the tethering and reduce the bulk of fatty tumor. Surgical treatment after neurological deterioration has poor unacceptable outcomes. With better understanding of the anatomy of spinal lipomas and advanced microneurosurgical techniques, surgery is safer and prevents long-term outcome. In children born with a lipomyelomeningocele mass surgical treatment is indicated when the patient reaches 2 months of age. Overall, with surgery, 19% will improve, 75% will be unchanged, and 6% will worsen, and foot deformities often progress regardless. The risks involved in surgery are also higher include CSF leak and infection

being as high as 10–20%, neurological deterioration from 2% to 7%,^{34–36} and retethering and late deterioration.³⁴

Fatty Filum or Lipoma of the Filum Terminale

This is defined as an accumulation of fat within the terminal filum with an incidence of 13–26%.³⁷ Radiologically, it is seen as a thickening of the filum >2 mm with fat deposition demonstrated on T1-weighted magnetic resonance imaging (MRI) (Fig. 20.8). The thickened filum can resist ascent of the conus medullaris causing tethering and occasionally contribute to neurological deterioration.

They usually form part of occult dysraphism with no cutaneous markers. They can occur alone or as part of a caudal regression syndrome during secondary neurulation, with involvement of cloacal and urogenital structures.^{38,39} They are usually asymptomatic until the adolescent growth spurt.

Back pain is the commonest symptom often exacerbated by stretching, physical activity, and trauma. These lesions are being commonly recognized after the routine use of MRI scans and the natural history is still not clear. Hence, the surgical management of fatty filum is debatable given the poor understanding of the natural history. The management is based on the presence of pain or neurological signs and the position of conus medullaris. When the filum is thick and the patient is symptomatic with low-lying conus the management is surgical division. Controversy, however, arises when the patient has

Fig. 20.9: Division of the thickened film terminable infiltrated with fat.

low-lying conus with no symptoms or a normal position of conus with symptoms of tethering. Given the low complication rate with this procedure, surgery is a reasonable option in this situation after a detailed discussion about the risk and outcome of the procedure with the patient (Fig. 20.9).

SPLIT CORD MALFORMATION

Split cord malformation (SCM) is an anomaly where the spinal cord is split over a portion of its length to form a double neural tube. The two hemicords may be contained within a single dural sheath, or each may be contained within its own separate dural sheath. Both have a common embryonic origin.

Type I SCM, otherwise commonly referred to as diastematomyelia, is defined as two hemicords, each with its

Figs. 20.12A and B: (A) Short split with a membranous peg clear of reuniting cords. The roots are seen medially. (B) Short and tight split cord malformation seen with traction of the cord with a higher auxiliary bony peg.

own central canal, lying within separate dural tubes, which are separated by fibrous (Fig. 20.10), or osseocartilaginous (bony) median septum. They have a single set of dorsal and ventral nerve roots (Figs. 20.13A to D). They may also present with duplicate spinal canals, duplicated neural arches with two pairs of pedicles at each level (Fig. 20.11). Other abnormalities of the spine at the level of the split are an absent disc and a dorsal hypertrophic bone where the median bony spike lies (Figs. 20.12A and B). Two-thirds of type I SCMs have overlying skin abnormalities and are

Table 20.2: Differences between the two types of split cord malformations.

Type 1: <i>Diastematomyelia</i>	Type 2: <i>Diplomyelia</i>
Cord split into two half with its own dural sheath	Cord split into two half within one dural sheath
Single lateral set of dorsal and ventral roots	Medial and lateral sets of dorsal and ventral roots
Midline bony, cartilaginous or fibrous tethering bands present	Usually none present
Associated with Spina Bifida, cutaneous markers, hydromyelia, Klippel–Feil syndrome, hydrocephalus, Arnold–Chiari malformation and intradural teratomas	Also associated with the same

associated with spina bifida, Klippel–Feil syndrome, Chiari malformation (CM) and intradural lipomas, and teratomas.

Type II SCM, referred to as diplomyelia, is defined as two hemicords within a single dural tube, separated by a nonrigid fibrous median septum. They usually have a dorsal and a ventral nerve roots arising from each hemicord. There is usually no spine abnormality at the level of the split, but there can be an associated spina bifida.^{5,40,41} Dystrophic median nerve roots projecting from one or both hemicords have been associated with both diastematomyelia and diplomyelia. The difference is summarized in Table 20.2.

Fig. 20.14: Split cord malformation with neurenteric remnants including the gut, fatty tissue and also liver.
Courtesy: Mr John Firth, Nottingham, UK .

Split cord malformations are usually located in the lumbar and the thoracic regions and are more common in girls^{6,42} with type I being more frequent than type II.⁴³ They typically produce neurological deficits after 43 months of age.⁴³ Spina bifida occulta can present in 50–80%. Midline thoracic or lumbar cutaneous abnormalities are common.

Various theories have been proposed for the development of SCM. Several theories hold good to explain a variety of midline anomalies composed of tissues derived from any of the three primary germ cell layers. During the notochordal split the remnants of the endodermal-ectodermal adhesion could give rise to endodermal remnants anywhere between the gut and the cutaneous ectoderm (Fig. 20.14). Visceral malformations are exceedingly common when the enteric contents are seen. If the neurenteric tract persists further dorsally to involve the ectoderm, an associated myelomeningocele can occur.

The most frequently occurring lesion is a hairy patch in 40–50% and others include lipomas, dimples, hemangiomas,

sinus tracts and fistulas, and meningocele or myelomeningocele. The level of the cutaneous skin lesion does not correspond to the level of the SCM. Spine deformity is more likely to occur with higher lesions and, when present, increases with age. The deformity is predominantly due to presence of hemivertebrae and spine bifida. The cord may be asymmetrically split with one leg shorter or underdeveloped with the corresponding thinner cord (Fig. 20.15). Similarly a syringomyelia when present usually is seen higher to the split and may occasionally extend into one of the hemicords. In 85% patients at least one lesion causing a spinal tether will be found with the cones lying below L2. The causes of tether include a thick film, fatty film, lipoma, dermal sinus tract, or a myelomeningocele.⁴⁴ A thickened film followed by a myelomeningocele is the commonest cause.

If a patient is asymptomatic, SCM does not require any treatment. When a patient is symptomatic from cord traction and dysfunction from a bony peg and tethering surgical resection of the bony spur followed by detethering of the film is required. If there is no bony peg then only detethering will be required. Most patients present with tethering of the cord and symptoms improve with untethering.⁴⁴ The other situation that is commonly encountered is a SCM in association with a vertebral deformity, which requires correction. In this situation the bony spur removal and detethering is performed as a primary procedure followed by a deformity correction 3–6 months later. Spinal cord monitoring can be used during the procedure. There is currently no literature to support performing both surgeries in the same setting.

DERMAL SINUS, DERMOID, AND EPIDERMOID CYSTS

Dermal sinus is defined as an epithelium lined fistula extending from the skin surface and can connect with the dura as well as the spinal cord. The sinus tract may terminate in the subcutaneous tissue, bone, dura, subarachnoid space, or film terminale. It may pass between normal vertebrae or through a bifid spine to attach to the dura. Infrequently, this can cause tethering of the cord.^{6,26} They result from a failure of the surface ectoderm and the dermal elements to separate from the neuroectoderm. They may appear as a dimple or a small sinus opening measuring about 1–2 mm in diameter. It can present with hair in the midline or paramedian and the surrounding skin may appear normal or pigmented “port wine stain.” Dermal

sinus tract may terminate in a dermoid or epidermoid cyst and can directly communicate with the dura as well as spinal cord in 11.3% of cases.⁴ This can cause either spinal cord or cauda equina compression or tethering effect.

A dermoid cyst is lined with dermis (skin appendages—hair follicles, sebaceous glands) and secretes sebum, while an epidermoid cyst is lined with stratified squamous epithelium containing keratin and cholesterol from desquamated epithelium. As a result this can predispose the contents of the tract to cause irritation and spread to the dura and cause chemical or infective meningitis (*usually Staphylococcus aureus*) that can be recurrent and less frequently intrathecal abscess and arachnoiditis. Less serious, local infections can occur. It is found more frequently in the lumbosacral region, although cervical, thoracic, and occipital locations are possible.^{4,5} They may connect to a fatty film, a low-lying conus medullaris, or an intraspinal lipoma. Pilonidal cysts are a different entity, which may also be congenital containing hair, are located superficial to the post sacral fascia, and may become infected.

When examining a baby for possible spinal dysraphism the natal cleft must be separated and examined for a small sinus or dimple hidden underneath. The incidence in neonates is approximately 1–2%, but the true incidence may be unknown. Dermal sinus tracts that are found above the natal cleft are usually directed superiorly (Fig. 20.16). Coccygeal pits or dimples are found within the natal cleft with a tract extend either straight down or inferiorly below the subarachnoid space. These may not need to be treatment unless they develop any signs of infection. Although these are seen at birth occasionally patients are not referred to medical attention until they develop an infection or meningitis as their first presentation. When seen at birth an ultrasound can be performed to look for a spina bifida or mass lesion intradurally. Magnetic resonance imaging best shows the underlying abnormalities and can track the sinus and its attachments. The previously proposed injection with contrast into the sinus should be avoided to precipitate infection.

Dermal sinuses above the gluteal crease should be surgically removed. Treatment of more caudally located sinuses is slightly controversial. Although approximately 25% sacral sinuses seen at birth will regress to a deep dimple it is recommended that the tract should be followed intradurally and the associated dermoid lesion should be excised (Fig. 20.17). There is no justification for a conservative approach as such a therapy risks the development of meningitis.

SACRAL AGENESIS AND CAUDAL REGERSSION SYNDROME

The filum terminale and the cauda equina are formed from the caudal part of the neural tube by regression. During the formation of the primitive streak the caudal end of the embryo forms a caudal eminence. This separates itself from neural tube and forms the film terminale, cauda, and conus medullaris by retrogressive differentiation. Failure of retrogressive differentiation may also give rise to lipomas and myelocystoceles. During this process, a localized dilation of the central canal, the ventriculus terminals,

arises in the cones. The caudal eminence also gives rise to the other structures including the anorectal canal (distal colon, rectum, and anus) and urogenital sinus (bladder, urethra, and genitalia). The cloacal membrane eventually ruptures to become a perforate anus. Cloacal folds ultimately differentiate into male or female genitalia. The conus medullaris initially rests in the coccygeal region and ascends with life to lie at the L2–L3 at birth and reaches its destination at the L1–L2 level by 3 months. Gestational diabetes plays a role in the embryogenesis of these malformations is particular.

Simple agenesis of the sacral and the coccyx to serious anomalies of the caudal spine involving the sacral spine, lower extremities, spinal cord (Fig. 20.19), genitourinary system and gastrointestinal tract have been described. Sacral agenesis is suspected by flattening of the buttocks, shortening of the intergluteal cleft, and prominent iliac crests. Based on the radiological appearance of sacrum, Pang classified sacral agenesis into five types. Abnormalities in the foot are suggestive of vertebral segmentation anomalies.

Sometimes a baby is born with significant and serious defects including omphalocele, cloacal artesian, cardiac problems, genitourinary problems, and tracheoesophageal fistula. They may require immediate operation and then followed by more detailed MR evaluation to look for spinal abnormalities. Tethering is a common finding (Figs. 20.18A and B) in 24% of children with anorectal malformations and in 43% of children with complex malformations. Myelocystocele or lipomyelomeningocele with tethered spinal cord present with a soft fatty mass in the lumbo-sacral region. Surgery for tethering should be performed

Figs. 20.18A and B: T2-weighted (T2W) magnetic resonance imaging (MRI) (A) and T1W MRI (B) showing sacral agenesis and caudal regression with a tethered and low-lying cord.

after improving the general condition of the child. Early untethering is associated with improvement in motor and sensory preservation and improvement.

SYRINGOMYELIA AND CHIARI MALFORMATION

Chiari Malformation

Chiari malformation (CM) is a malformation of the posterior fossa of the brain. It consists of a downward displacement of the cerebellar tonsils through the foramen magnum (FM). The displacement is generally about 5 mm or more. The true incidence of this malformation is unknown. In a study of the 22,591 patients who underwent MRI of head, 175 (0.775%) were found to have tonsillar herniation extending >5 mm below the FM.⁴⁵ Various authors have reported a familial incidence ranging from 3% to 12%.^{46,47}

The development of the deformity has a genetic basis. This is supported by the presence of a familial incidence. However, the exact cause for this deformity has not been clearly elucidated. Various theories have been postulated to explain the development of features seen in CM. Williams⁴⁸ suggested that the pathogenesis is due to the differential cranial-spinal pressure gradient across the FM. This led to an altered CSF circulation at the FM, which prevented instantaneous pressure equilibration between the intracranial and the spinal subarachnoid space. This results in development of an intermittent vector force,

which, with each Valsalva maneuver, leads to the progressive downward movement of developing tissue through the FM. This craniospinal dissociation most accurately accounts for most of the features associated with the CM and also explains the basis of the current form of proposed treatment, i.e. posterior fossa decompression.^{48,49} Schady et al.⁵⁰ found that the posterior fossa volume was 23% smaller in patients with CM I than in controls thus suggesting that the herniation occurred due to the mismatch between the rapid growth of the brain during the first year with a small developmental posterior cranial fossa.

Types of Chiari Malformations

Hans Chiari, an Austrian pathologist, was the first to describe this entity in 1896, following postmortem examinations. He initially described Chiari types I, II, and III; he later added type IV. Chiari type I, is characterized by a displacement of the cerebellar tonsils 5 mm below the FM or at C1 level and rarely below C2–C3. Hydrocephalus is reported in 3–10% of the patients with Chiari type I malformation. A more frequent observation is syringomyelia, reported in 50–75% of cases (Fig. 20.20). Syrnix cavities are usually found in the cervicothoracic spinal cord. Approximately 50% of Chiari I present with basilar and craniovertebral anomalies, the most common being basilar invagination and occipitalized Atlas. Abnormalities of the fourth occipital sclerotome appear to be closely related to hindbrain malformation, which are often seen

Fig. 20.20: Chiari malformation with tonsils at below the C1 posterior arch with a syringomyelia.

in conjunction with CM. Other commonly seen osseous lesions include platybasia, atlantoaxial dislocations, and Klippel–Feil anomaly. In CM II the displacement not only includes the cerebellar tonsils, but also the vermis, fourth ventricle and lower brain stem below the level of FM. Almost all cases of myelomeningocele present with Chiari II, though the reverse is not true all the time. Hydrocephalus is seen in 90% of the cases and ventricles are seen asymmetrical. The fourth ventricle is small and deformed. Syringomyelia and bony abnormalities in the upper cervical spine shows Klippel–Feil anomaly with hypoplastic posterior arch of C1. Chiari malformation III remains as a rarely identified entity, which includes all of the characteristics found in CM I and II and also includes a herniation of cerebellum in a occipitocervical encephalocele.⁵⁷ Chiari malformation IV is characterized by marked cerebellar hypoplasia or aphasia and tentorial hypoplasia. There is no hindbrain hernia ion. It is very rare and is noncompatible with life.

Recently more “Complex Chiari” malformations have been defined as with radiographic findings of brainstem herniation through the FM, medullar kink, retroflexed odontoid, abnormal clival–cervical angle, occipitalization of the atlas, and basilar invagination. Detailed evaluations using current imaging methods have introduced more subtle forms of the malformation currently named as Chiari 0 and Chiari 1.5 and have also introduced terms like “asymptomatic” and “incidental” CM depending upon the extent of cerebellar ectopia and clinical findings. In Chiari 0 there is minimal or no hindbrain herniation

and syringomyelia. Many of them show cranial–cervical abnormalities of type I and at surgery reveal arachnoids adhesions and bands with a crowded FM. A more recent entity of Chiari 1.5 has been described, and it specifically concerns with patients with tonsillar herniation but without brainstem elongation or fourth ventricle deformation.

Clinical Presentation

The clinical presentation with CM I in early childhood differs from the clinical features observed in the adult patient population. Children younger than 3 years present with oropharyngeal dysfunction, such as aspiration, regurgitation, choking, dysphagia and abnormal vocal cord function. Chronic cough is thought to be the major presentation in children younger than 3 years of age. While older children present with headache and scoliosis. Park et al.⁵⁸ found pain to be the most common feature in (63%), numbness (26%), motor weakness (19%), and in-coordination (16%). In the older group of adolescents, 91% presented with pain, 27% had scoliosis. In a large series of adult patients, 81% presented with suboccipital headache, distinctively worsening on physical exertion and Valsalva maneuvers, head dependency, and posture changes.⁴⁵ Patients with CM II almost all cases present with myelomeningocele. The common presentation features consist of lower cranial nerve deficits, cerebellar dysfunction, and respiratory difficulty. With increasing severity in Chiari II respiratory insufficiency and apnea contribute to mortality. Progressive tethering and/or formation of syrinx usually starting from the site of myelomeningocele repair produce progressive neurological deficits in this group. Chiari III malformations are the rarest form of hindbrain deformities characterized by occipital and/or cervical encephalocele. These children present with severe neurologic deficits including delayed milestones, seizures, ataxia, spasticity, and other features common to Types I and II. They are rare and fatal in early infancy.

Treatment of Chiari Malformation

Periodic neurologic examinations with imaging evaluations are favored for asymptomatic Chiari I, especially, when the syrinx is <2 mm. Surgical intervention is favored for the symptomatic cases. The current practice involves suboccipital bony decompression including FM and C1 posterior arch, followed by opening of the durra with

release of all arachnoid adhesions and augmentation with duraplasty to facilitate CSF circulation around the cranio vertebral region. In all cases, the thickened arachnoid membrane bridging the cerebellar tonsils are released, and the cerebellar tonsils are coagulated to shrink the size and improve the volume of posterior cranial fossa. The fourth ventricle is visualized by gentle dissection and any adhesions released. The treatment for Chiari type II includes repair of the myelomeningocele and treatment of hydrocephalus by placing a shunt tube. The changes due to brainstem deformity do not show improvements with surgical correction or shunting of hydrocephalus and thus tend to produce progressive neurological worsening. Periodic evaluations for brainstem malfunction need to be performed, especially for respiratory function, swallowing and speech. If progressive brainstem compression is clinically evident, posterior fossa decompression is indicated in such cases.

Syringomyelia

It is a term applied to a progressive disorder of the spinal cord characterized by cavitations in its substance, presenting clinically as a syndrome of lower motor neuron signs in upper limb, upper motor neuron signs in lower limb, and segmental dissociative sensory loss. In syringomyelia, cavitations outside the central canal are seen and it is not lined by ependyma. Syringomyelia can either be communicating with the fourth ventricle and the central canal as seen in CM and basilar arachnoiditis or noncommunicating as in spinal cord tumor, spinal cord trauma, and spinal arachnoiditis.

Based on the etiology, Barnett's classified syringomyelia as follows:

- Associated with congenital anomalies of the FM and posterior fosse (Chiari syndrome, dandy walker syndrome and basilar invagination).
- Associated with acquired basal abnormalities, such as basal arachnoiditis, posterior fossa tumors.
- Post-traumatic.
- Associated with spinal tumors.
- Idiopathic.

Clinical Presentation

It is commonly present in the second and the third decade. In early stages, complaints include pain in the cervical region and occipital region related to coughing and sneezing, numbness in the upper limbs and trunk

associated with weakness in the upper limbs and difficulty in walking due to myelopathy. Syrinx may extend into the medulla, producing a syringobulbia characterized by dysphagia, nystagmus, vertigo, tinnitus, deafness, pharyngeal and palatal weakness, asymmetric weakness and atrophy of the tongue, and sensory loss involving primarily pain, and temperature senses in the distribution of the trigeminal nerve. Dysesthetic pain, which can be very troublesome usually, involves the neck and shoulders, but may follow a radicular distribution in the arms or trunk.

Signs include structural features, such as scoliosis, hemiatrophy, asymmetry of the face and upper limbs. Patients may have features of spinal dysraphisms. Charcot's joints due to sensory deficits are commonly seen in the upper limb. Klippel-Feil deformity with features of decreased neck movements, low hairline, and short neck may be evident. The expanding cavity disrupts the decussating spinothalamic fibers that mediate pain and temperature sensibility, resulting in loss of these sensations, while light touch, vibration, and position senses are preserved. This may be lost in one or both arms. As the cavity enlarges further it involves the posterior columns with loss of position and vibration senses in the feet, astereognosis may be noted in the hands. When the extension is into the anterior horns it damages motor neurons causing diffuse muscle atrophy that begins in the hands and progresses proximally to the shoulder girdles. Claw hand may develop in late stages. Painless ulcers of the hands and sometimes the foot are frequent. Neuropathic joints (Charcot joints) may affect the shoulder, elbow, or wrist.⁵⁹ Scoliosis is seen sometimes.⁶⁰ Acute painful enlargement of the shoulder is associated with destruction of the head of the humerus as in Figures 20.21A to D.

Scoliosis Associated with Chiari Malformations and Syringomyelia

Scoliosis is the most common musculoskeletal deformity seen in cases of Syringomyelia and Arnold-Chiari malformations. The postulated mechanisms for development of the spinal deformity have not been clearly elucidated, although several theories have been proposed. Some authors have suggested the idea of an asymmetrically enlarging cyst that injures either the lower motor neurons or the dorsomedial and the ventromedial nuclei of the gray matter of the anterior horn of the spinal cord, thereby creating imbalance of trunk musculature and predisposing to scoliosis.^{51,52} Gardner et al.⁵³ suggested

Figs. 20.21A to D: Patient with Type 1 Chiari malformation and a neuropathic left shoulder. (A) T1 weighted (T1W) MRI shows tonsils at the level of C1. (B) T2 weighted (T2W) MRI shows a thin syrinx extending below cervical spine. (C) X-ray of shoulder showing destruction of the humeral head. (D) 3-D reconstruction showing a Charcot's shoulder.

that during fetal development, the mass effect of the syrinx caused vertebral deformity, resulting in scoliosis. Thus, the lack of understanding of the pathophysiology of scoliosis in syringomyelia makes it difficult to determine the effect of syrinx on the natural history of the spinal curve.

Scoliosis associated with syringomyelia has been noted with several findings, including young age of presentation, atypical curve, rapid curve progression, and back pain. The presence of a syrinx complicates the treatment of scoliosis, because spinal distraction and instrumentation have been associated with an increased risk for neurologic deficits.

Predictors of Curve Progression

The natural history of scoliosis in syringomyelia and CM has not been clearly defined. Flynn et al.⁵⁴ in a 15-year retrospective institutional review concluded that progression of spinal deformity after neurosurgical management of Chiari I malformation was associated with age >8 years at neurosurgical decompressions and initial neurologic symptoms, double scoliosis curve patterns, kyphosis, rotation, rigid curves, and larger curve at presentation. Chiari

malformation and syringomyelia benefit from suboccipital craniectomy prior to deformity correction surgery. It gives best chance for syrinx reduction and scoliosis improvement, particularly in children younger than 10 years.⁵⁵ Syrinx shunting surgeries do not afford any benefit, as they do not improve the scoliosis. Cases with congenital scoliosis or myelomeningocele, neither stand to benefit from the neurosurgical procedure since the cause of the curve remains untreated.⁵⁵ Krieger et al.⁵⁶ in review of 79 cases concluded that patients who presented with scoliosis and were found to have a CM I with a syrinx, a CM I decompression alone was adequate treatment for mild scoliosis of <20°. For patients with curves greater than 25°, the risk of curve progression is high even after a CM I decompression and syrinx resolution, with 70% (21 of 30 patients) in this subgroup requiring further orthopedic treatment of bracing or surgery. Age greater than 10 years generally is associated with curve progression irrespective of suboccipital decompression.

Resolution of Syringomyelia

Syringomyelia is seen in >80% of patients with CM. The effects of suboccipital decompression on resolution of syringomyelia are more consistent as compared to the effect on scoliosis. The efficacy of CM I decompression in terms of syrinx resolution, neurological improvement was demonstrated by Kreiger et al.⁵⁶ with MRI studies. They demonstrated resolution of the syrinx 6 months postoperatively in 87% of the patients, resolution of the neurological findings was seen in 80% of the patients and 69% had resolution of headache symptoms after suboccipital decompression. We have shown two patients with resolution of syrinx following suboccipital decompression (Figs. 20.22 and 20.23).

TETHERED CORD SYNDROME

Tethered cord syndrome (TCS) is been defined as a spectrum of congenital anomalies resulting in an abnormally low position of the conus medullaris, usually lower than the L2 vertebra or below the L1-L2 disc space,⁶¹ that may lead to neurological, musculoskeletal, urological, or gastrointestinal abnormalities. Classically, the film terminable is thickened with low-lying cones whose symptoms improved following detethering. Currently, a more accepted diagnosis of TCS is defined as a pathological fixation of the spinal cord in an abnormally lying position.⁶¹ Most recently, TCS has been described to have the cones at a

Figs. 20.22A and B: Pre- (A) and postoperative (B) picture of a type I Chiari malformation with syringomyelia shows good resolution of the syrinx cavity following foramen magnum decompression.

Figs. 20.23A and B: Pre- (A) and postoperative (B) picture of a type I Chiari malformation with syringomyelia shows good resolution of the syrinx cavity following foramen magnum decompression. Postoperative pseudomeningocele is seen.

normal position on imaging but with signs and symptoms consistent with TCS. They have associated findings such as cutaneous stigmata, vertebral abnormalities, intradural lipoma and neurological abnormalities on examination. Among these patients, symptoms of pain and bowel or bladder incontinence appeared to be responsive to detethering.

During development distal to the posterior neuropore, undifferentiated cells from the primitive streak form the caudal cell mass that develops into the conus medullaris, cauda equina, and film terminale. During the end of the canalization period (days 43–48), the ventriculus terminalis forms at the terminal end of the neural tube near the coccyx.⁶² Neural tissue caudal to the ventriculus terminalis undergoes retrogressive differentiation to form the film terminale and cauda equina. Simultaneously, the vertebral column grows at a disproportionate rate to the spinal cord, resulting in the ascension of the cones and elongation of the filum. The cauda equina forms, as nerve roots grow longer to accommodate the differential growth. The regression process continues into the postnatal period with the cones reaching the adult level of L1–L2 by approximately 3 months of age.

The pathophysiology of TCS involves the existence of traction and the loss of the elasticity of the filum terminale as well as ischemic insult to the cord. The extension of the spinal cord, the metabolic abnormalities observed, and the decrease in spinal cord blood flow leads to neurological

deficits.^{63,64} Tethered cord syndrome can either be primary when associated with congenital abnormalities of the cord or secondary tethering following intradural surgery for congenital abnormalities or tumors.

Clinical Presentation

Toddlers and Young Children

Back and lower extremity pain may be a presenting complaint in this age group, associated with both motor and sensory dysfunction. Delay in developmental milestones in toddlers, while gait difficulties, bladder disturbances, sensory deficits, development or progression of scoliosis, or foot deformities in older children may reveal clues to TCS. Sensory loss tends to occur in a nonsegmental distribution.

Older Children and Teenage

Nondermatomal pain in the lumbosacral region, perineum, and legs with activity is the predominant symptom. Progression of a scoliosis deformity often contributes significantly to complaints of pain. Urinary incontinence may also be a predominant symptom.

Adults

With a known history of spina bifida, the clinical presentation is similar to that in adolescents with exacerbation of

pain and sphincter dysfunction related to activity. Weakness may be subtle and present only in a single muscle group. In adults who present without a previous history of spina bifida, pain is the most common presentation followed by weakness, unsteady gait, and urological dysfunction. A history of sexual dysfunction may be the only presentation with TCS in adults. Other uncommon presentations are chronic fatigue, perineal pain, patchy sensory loss including the sacrum and recurrent bladder infections. In the patients without orthopedic deformities or urological dysfunction, trauma often leads to new onset of symptoms. The trauma may be mild (child birth, exercise) or involve a major direct trauma to the spine. Trauma increases the stress on the already tense spinal cord, altering microcirculation and cellular metabolism and eventually leading to neurological deterioration.

Examination

Newborns and children with TCS may have cutaneous markers suggesting investigation for underlying problems. The frequently seen cutaneous markers are myelomeningocele sac, cutaneous hemangioma, hypertrichosis, subcutaneous lipoma, dimple and dermal sinus, and pigmented nevus. Patients often have more than one symptom or sign (Fig. 20.25). However, one of the clinical features is usually predominant over the other. Some of the common clinical signs are weakness of the lower limbs, absent reflexes, muscle atrophy followed by spasticity, and contractures in extreme cases, patchy sensory loss, bowel and bladder dysfunction, and rarely tropic painless ulcers in ankle and foot.

Diagnosis

Magnetic resonance imaging is the radiographic modality of choice for evaluating TCS. Magnetic resonance imaging demonstrates the level of the conus, often visualizes the cause of tethering, and provides detail for potential surgical planning (Figs. 20.26A to C). Common lesions seen on MRI associated with TCS, including meningoceles, and myelomeningoceles, SCMs, dermal and lipomatous tumors, are all readily demonstrated on MRI. Thickness of the film terminale greater than 2 mm is considered abnormal in children. Urodynamic studies are useful in assessing the bladder capacity, pressure, electromyogram activity, and sphincter function. Detrusor hyper-reflexia,

reduced bladder compliance, dyssynergia, and decreased sensation can be detected.⁶⁵ In patients with abnormal urodynamic testing, whether clinically symptomatic or asymptomatic, improvement from 29% to 75% has been reported following detethering in a broad range of patients. Urodynamic tests have been used as a marker to document improvement or stability of function following a detethering procedure.

Surgery

The most common age at presentation is between 5 and 9 years, concurrent with the period of rapid growth. Untethering involves the release of filum terminale between the L5-S1 or S1-S2 interlaminar space. This is fairly a safe surgery in experienced hands and best operate under microscope to visualize the film.⁶⁶ The film is differentiated from the roots by the pale color and a single tortuous vessel that runs on it with a tether (Fig. 20.24). The aim of the surgery is to deal with the local pathology; however, recurrent tethering can produce symptoms. In adult population, the rate of retethering has been quoted to be as high as 25%. It aimed to prevent further neurological deterioration and to allow functional improvement. Untethering can improve back and leg pain in 78% and 83%, respectively. However, motor weakness will stabilize or improve in only 27% and 64% of patient, respectively. Sensory deficits remained unchanged in 50% of patients. Urological abnormalities improved in 50% of patients undergoing unfettering and remained stable in 45%.⁶⁶ Untethering of the spinal cord after a previous myelomeningocele repair is, however, challenging because the structural and functional anatomy is distorted due to both developmental anomalies and scar from previous surgery. The placode and functional nerve roots can be difficult to distinguish from scar, which can be, tethered themselves, placing the patient at significant risk of neurological deterioration from the procedure.⁶⁷ It is imperative that symptomatic secondary tethered cords are recognized early because delayed recognition is associated with irreversible injury (Fig. 20.27). Although, radiographically demonstrated spinal cord tethering occurs in nearly all patients after repair of spinal dysraphisms, not all patients are symptomatic. Retethering of the cord has been considered to be very rare. The risk of tethering can vary according to the patient's age, the type, and the severity of the entire condition. In children the risk of retethering is higher (20%) compared to adults (5–10%) due to the shallow canal.

INTRODUCTION

Occult spinal dysraphism (OSD) refers to a group of disorders arising as a result of incomplete formation of the midline dorsal neural, mesenchymal, and cutaneous ectodermal structures during embryogenesis. Depending on which embryonic layer is involved, there can be abnormalities in the skin or osseous or neural elements. The term “occult” is used to distinguish these lesions from the open group of neural tube defects called spina bifida aperta (e.g. myelomeningocele). The term “occult,” however, is misleading due to the fact that the majority of these conditions are associated with some abnormalities of the overlying skin. The OSD has come to encompass a large group of lesions that include lipomas, lipomyelomeningoceles, split cord malformations (SCMs), dermal sinus tracts, neurenteric cysts, dermoids, and tight terminal filum.

One of the most common associated syndromes with OSDs is tethered cord syndrome (TCS). Spinal dysraphisms can limit the normal rostral movement of the spinal cord during development and lead to traction on the spinal cord. This may cause progressive neurologic, urologic, and orthopedic deterioration. The focus of this chapter will be on the various common forms of OSDs and the clinically associated syndrome of the tethered spinal cord.

LIPOMAS/LIPOMYELOMENINGOCELE

Spinal cord lipomas are among the most common single dysraphic lesions that often present with TCS. The incidence

of lipomas has been reported to be one in 4,000 live births.¹⁻³ They are responsible for approximately 25–30% of cases of the tethered cord in children.^{4,5} Spinal cord lipomas tether the spinal cord because they are attached to the neural elements and the subcutaneous fat, posterior elements, or thoracolumbar fascia through a defect in the dura (Fig. 21.1).

There are several different types of spinal cord lipomas: those that involve the conus and those that involve the filum. Chapman’s classification system divides spinal cord lipomas into three categories: dorsal, transitional,

Fig. 21.1: T1 (left) and T2 (right) magnetic resonance imaging of the lumbar spine demonstrating a lipomyelomeningocele, low-lying conus and tethered cord.

and terminal.⁶ Dorsal and transitional lipomas contain a stalk that extends from the normal subcutaneous fat through a dorsal midline defect in the posterior elements (lamina), lumbodorsal fascia, and dura to attach directly to the spinal cord. In dorsal lipomas, the stalk inserts dorsally into the spinal cord with normal dura and cord caudal to it. However, in transitional lipomas, the stalk blends into the terminal conus with no normal cord caudal to it. Terminal lipomas attach to the most distal part of the conus with the lipoma either replacing the filum completely or separating it from the conus by a thickened filum. The dura and lumbodorsal fascia are intact with the sacral roots exiting the conus above the lipoma.^{6,7}

Transitional lipomas are the most common type of lipomyelomeningocele, representing approximately 64–75%, while terminal lipomas account for approximately 13–26% of all spinal cord lipomas.^{8,9} The rarest are the dorsal lipomas that are found in <10% of all cases.

The embryologic defect responsible for spinal lipomas occurs between the time of primary neurulation (neural tube closure) and secondary neurulation (formation of the terminal spinal cord). Differences in the timing and location of the defect are thought to lead to different spinal lipomas. The error is believed to be premature dysjunction between the cutaneous and neural ectodermal layers prior to the neural tube closure. Mesenchymal cells migrate through the focal site, prevent further closure of the neural tube, and differentiate into a lipomatous mass.¹⁰ Dorsal lipomas are thought to be a result of a transient interruption of the primary neural tube closure, resulting in a segmental abnormality. On the contrary, the complete involvement of the entire conus in transitional lipomas suggests that not only is primary neurulation involved, but that secondary neurulation is also affected. The rostral part of the transitional lipoma arises from aberrant primary neurulation, whereas the caudal part arises from abnormal secondary neurulation. In terminal lipomas, the error is believed to be in secondary neurulation because the segments formed during primary neurulation (above S2) are not involved and there is no dorsal dural defect. Also, the lipoma is part of or replaces the filum, which is formed during secondary neurulation.¹¹

Lipomas and lipomyelomeningoceles can cause neurologic dysfunction by abnormally forming neural structures, mass effect on the spinal cord, or traction by tethering the spinal cord to the surrounding structures during development.¹² Children with spinal cord lipomas tend to present with neurologic deficits by 2 years of age.¹³

Fig. 21.2: Photograph demonstrating hypertrichosis of the lumbosacral region.

These patients often deteriorate or become symptomatic during periods of rapid growth or activities that stretch the spine.⁵ These include activities where there is a disproportionate lengthening of the vertebral column in relation to the spinal cord that is tethered. Also, direct trauma to the subcutaneous portion of the lipoma can result in severe pain and dysesthesias, followed by neurologic deficit.¹³

Cutaneous abnormalities indicative of lipomyelomeningoceles or lipomas often occur in the midline of the back near the level of the spinal lesion. They include subcutaneous lipomas, capillary hemangioma, skin dimples, hairy patches, and skin appendage¹³ (Fig. 21.2). The incidence of cutaneous stigmata in patients with spinal cord lipomas is about 70%.¹ Subcutaneous lipomas are present in about 60% of cases of lipomyelomeningoceles.^{14,15} About 20–30% of intradural lipomas are associated with cutaneous stigmata without an obvious subcutaneous lipoma.¹³ In contrast to dorsal and transitional lipomas, terminal lipomas are the most likely to have no cutaneous stigmata of spinal dysraphism.¹⁶

Neurologic deficits, urologic dysfunction, and orthopedic deformities are commonly seen with spinal lipomas. Motor deficits can present in infants, toddlers, and older children. They can present as asymmetric movements, atrophy of muscles, delay in motor milestones, or discrete muscle weakness.¹³ Although one side tends to be worse, both sides are affected. Bowel and bladder dysfunction is commonly seen in patients with spinal cord lipomas. Urodynamic testing may reveal abnormalities in 33–66% of children younger than 1 year of age.¹¹ Common symptoms

include delayed toilet training in younger children and urgency, frequency, and poor voluntary control in older children. The most common urodynamic abnormalities are flaccid bladder, detrusor sphincter dyssynergia, and detrusor hyperreflexia.^{14,17} Orthopedic abnormalities include foot deformities, asymmetric leg length, hip subluxation, scoliosis, and vertebral anomalies.¹¹ Progressive foot deformities are one of the most common presenting features of children with spinal cord lipomas.^{18,1,19} They include hammertoe deformity, varus or valgus deformity, exaggeration of arches, asymmetric foot size, and trophic foot ulceration. Scoliosis is seen in 10–25% of patients with spinal lipomas.^{11,13} This form of scoliosis, which is usually related to tethering of the spinal cord, lacks the rotational deformities that are seen with vertebral body anomalies.¹¹ In patients with congenital scoliosis, 18% were found to have OSD.²⁰ Congenital spinal defects can involve the laminae, pedicles, disc spaces, vertebral bodies, and the size and number of vertebrae. It is recommended that the spinal cord be detethered prior to any deformity correction of the spine to prevent neurologic deterioration.

The natural history of spinal lipomas has not been well delineated. However, most pediatric neurosurgeons would advocate surgical intervention for symptomatic patients regardless of the type of lipoma.^{8,9,17} In these instances, the patient's symptoms either stabilize or improve. In asymptomatic patients, the recommendations are not so clear. Some authors advocate prophylactic surgery in an attempt to prevent neurologic deterioration in the future.^{14,15,8,17} Two main reasons to support this view are a direct relationship between progressive neurologic deterioration and increasing age, and an 85% deterioration rate in children with untreated lipomas by 5 years of age.^{15,21} On the contrary, some authors advocate observation only for asymptomatic patients since the natural history is not evident and the associated surgical morbidity is high.^{22,9} Once the decision to operate has been made, the two primary objectives of surgery are to detether the spinal cord and reduce the mass effect by debulking the lipoma. These procedures have been made more safe with the use of intraoperative neuromonitoring and the laser.

SPLIT CORD MALFORMATIONS

Split cord malformation is a rare closed neural tube defect where the spinal cord is split into two halves of variable size. It is an occult form of spinal dysraphism in which the intervening tissue between the split cord causes tethering

Fig. 21.3: Axial T2 magnetic resonance imaging demonstrating type II split cord malformation with two hemicords in one dural sleeve.

of the spinal cord. This may lead to progressive neurologic, urologic, or orthopedic deterioration.

According to Pang, SCM is believed to be caused by an error of development during the time that the primitive neurenteric canal closes. There is formation of an abnormal accessory neurenteric canal connecting the yolk sac to the amnion through the midline embryonic disc that splits the notochord and neural plate. This canal then forms an endomesenchymal tract that splits the spinal canal longitudinally for a short distance. The tract develops into a midline septum, and the tissue surrounding the tract forms into two hemicords.²³

Split cord malformations have been divided into two main categories based on the number of dural tubes and the composition of the intervening midline septum. According to the Pang's classification, SCMs are of two types based on the composition of the dural coverings and intervening tissue.^{24,25} In SCM type I (formerly known as diastematomyelia), there is an extradural bony or fibrocartilaginous spur that divides the spinal cord into two halves with two different dural sleeves. In SCM type II (formerly known as diplomyelia), there is no bony septum but an intradural fibrous band and a common dural sac (Fig. 21.3). The type I septum almost always extends directly anterior to posterior.^{26,27} On the contrary, the type II septum is often obliquely or even coronally directed, dividing the anterior and posterior hemicords. In both types of SCM, the septum is the most caudal margin of the split with hemicords that can extend rostrally for many segments above the septum. Type I SCM is often

Figs. 21.4A and B: Axial CT (A) and axial T2 magnetic resonance imaging (B) demonstrating type I split cord malformation with two hemicords and two dural sleeves with an intervening bony septum.

associated with bony abnormalities, such as bifid vertebral bodies or congenital bony fusion (Figs. 21.4A and B). Type II SCM is the bony anatomy that is usually normal. Type I SCM is usually found in the thoracolumbar spine, whereas type II SCM can be seen anywhere.²⁵

Split cord malformation can be associated with scoliosis and other intraspinal anomalies. Congenital scoliosis is the most common clinical manifestation and is associated with 60–84% of patients with SCM.^{28,29} Common anomalies found are syringomyelia, myelomeningocele, lipoma, teratoma, neurenteric cyst, and low-lying conus.^{30–34} Secondary to these features, magnetic resonance imaging (MRI) should be performed in all patients with SCM or atypical scoliosis. Atypical scoliosis consists of left thoracic curves, a large curve at a young age, associated pain or neurologic deficits, thoracic kyphosis $>40^\circ$, or less rotation than is expected.^{35–39}

There are many cutaneous stigmata of SCMs, including hairy patch, capillary hemangioma, and dermal sinus tract. The most common is a large patch of hair overlying the defect (called “fawn’s tail”) and can be found in over half of all patients with SCM.^{40,41,25} Patients with SCM also have associated abnormalities of the musculoskeletal system, including scoliosis, asymmetry of the lower extremities, and cavus foot.

The clinical presentation of SCM differs in children from that in adults. In children, the onset is slow and insidious progressive neurologic deterioration. They can have painless loss of sensorimotor function, weakness of extremities, spasticity, and difficulty with ambulation.²⁵ In adults, SCM usually presents suddenly after an event, such

as a fall with dysesthesia or, less frequently, weakness. Bladder involvement in the form of urgency, frequency, or recurrent urinary tract infections is also commonly seen.^{42,43}

The indications for surgical intervention of SCM include any sign of tethered cord or neurologic compromise since the symptoms are usually progressive. In children with SCM, the risk of neurologic and orthopedic problems arising increases with age. For this reason, some authors advocate that the spines of all young children with SCM should be surgically explored.^{44,25} Prior to any surgical intervention, a computed tomography (CT) and MRI should be performed to provide a good understanding of the size and shape of the septum and vertebral body anomalies and to rule out any additional tethering lesions.

DERMAL SINUS

Dermal sinus tracts are the most representative of all OSD lesions. Spinal dermal sinus tracts consist of an epithelial-lined tract extending from the skin surface to the spinal fascia, dura mater, or spinal cord. These lesions may be found anywhere along the midline of the neural axis, although the lumbar and sacral areas are the most common. They are often confused and difficult to distinguish from benign congenital dimples. The incidence of dermal sinus ranges from 3% to 36%.⁴⁵ They can be solitary or combined with other manifestations of dysraphism. Dermal sinus tracts can be found in 15–40% of SCMs.²⁵

Dermal sinus tracts are often associated with tumors that can be found anywhere along the sinus tract. They in-

clude dermoids, epidermoids, and teratomas. Tumors can be found in 60% of all patients with dermal sinus tracts, with dermoids being the most common (83%).⁴⁶⁻⁴⁸ In addition, any element of cutaneous ectoderm can also be found along the tract, such as sweat glands, sebaceous glands, and hair follicles.

Dermal sinus tracts are remnants of incomplete neural tube closure. They result from incomplete separation of neural ectoderm from epithelial ectoderm, also called incomplete dysjunction. Dermal sinus tracts are unusual in that they occur after primary neural tube closure. The failed separation between the cutaneous ectoderm and neural ectoderm results in a tubular tract as the remaining vestige of the connection between these two layers. Because the neural tube closure was completed normally, the brain and spinal cord are usually well-formed and the child is neurologically normal at birth.

Like all other OSDs, dermal sinus tracts are also associated with cutaneous stigmata (Fig. 21.5). The six most common cutaneous findings associated with dermal sinus tracts include cutaneous dimple or pit, flat capillary hemangioma, hairy patch, dorsal dermal appendage, subcutaneous lipoma, and atretic meningocele.⁴⁹⁻⁵² True dermal sinus tracts can be found anywhere along the midline of the neuroaxis. However, the majority of these lesions are located in the lumbar or sacral areas. Tracts in the cervical and thoracic spine make up only 11% of all cases.⁵³

Dermal sinus tracts can often be confused with benign congenital sacroccygeal dimples. Simple dimples that are <5 mm in diameter, midline in location, overlie the coccyx, are hidden deep within the gluteal cleft, and are within 2.5 cm of the anus are not associated with OSD. However, 40% of atypical dimples such as those >5 mm in diameter, >2.5 cm from the anus, or associated with other cutaneous stigmata are associated with OSD.⁵⁴

The clinical presentation of dermal sinus tracts is usually infection or tethered cord. Infections can manifest as meningitis, draining tracts, or even intramedullary spinal cord abscesses.⁵⁵ Almost all of the spinal cord tethering occurs with dermal sinus tracts that are located in the lumbar or sacral areas.⁵⁶ Symptoms can include back pain, radiculopathy, weakness, sensory deficits, bowel or bladder changes, and foot deformities.

Once a dermal sinus tract is identified, surgical exploration and excision are recommended. Preoperative imaging, such as CT or MRI can be useful in identifying any intradural lesions or masses. It can also help delineate the extent of the tract course. In infants <6 months of

Fig. 21.5: Photograph demonstrating the cutaneous lesion in a patient with a dermal sinus tract.

age, ultrasound can be a very useful screening tool. It is portable, noninvasive, requires no sedation, and takes advantage of the cartilaginous vertebral arches in the infant.⁵⁷ The goals of surgery are to disconnect the neural elements from the skin surface, avoid infection, detether the neural elements, and excise any intradural masses.

TETHERED CORD SYNDROME

The term “tethered cord syndrome” was initially used to describe when an abnormally short and thickened filum terminale causes the conus medullaris to become caudally displaced.¹⁹ Currently, the term is used to describe any progressive neurologic, urologic, or orthopedic problem caused by a spinal dysraphism that limits the normal rostral movement of the spinal cord during development.¹⁵ The underlying pathophysiology for spinal cord tethering is mechanical traction that causes damage in a cumulative and insidious pattern. Spinal cord traction impairs mitochondrial oxidation and disrupts axonal transport that makes it susceptible to injury.⁵⁸⁻⁶⁰

The TCS can be divided into two main groups: congenital and acquired. Congenital TCS is described in the setting of OSDs where a lesion tethers the spinal cord during normal development. Some examples include lipomas/lipomyelomeningocele, dermal sinus tracts, and SCMs. Acquired TCS occurs following surgical repair of a myelomeningocele, infection, or trauma that may lead to scar formation and tethering of the spinal cord. Regardless of the etiology, free and rostral movement of the spinal cord is restricted with mechanical traction.

The clinical presentation of TCS is variable. Some children are completely asymptomatic but come to medical attention for the midline cutaneous stigmata identified on their back. Some examples of these include sacral dimple, capillary hemangioma, hypertrichosis (hairy patch), subcutaneous lipoma, gluteal asymmetry, or skin appendage. These are often the signs of OSDs. Some of these lesions can be pathognomonic for certain OSD. For example, hypertrichosis occurs in 65% of type I SCMs and subcutaneous lipomas or skin appendages occur in about 80% of spinal lipomas.^{9,61}

Neurologic symptoms that occur in patients with OSD range from simple back or leg pain to weakness and sensory deficits. Motor and sensory deficits are often subtle and progressive in nature. Some early signs may be delay in walking, unilateral atrophy of leg muscles, or an intorted foot. One common feature of neurologic deficits is that they are usually asymmetric regardless of the type or location of the spinal lesion.⁶² Spasticity, increased tone, and hyper- or hypoactive reflexes may be present.

Urologic and bowel dysfunction are common presenting symptoms of OSD. In older children and adults, the most common presenting urologic complaints are frequent urinary tract infections, urgency, frequency, enuresis, and incontinence. Urologic dysfunction is reported in about 70–87% of children with OSD. Common presenting scenarios include delayed toilet training, enuresis, and recurrent urinary tract infections. Fecal incontinence and constipation may also coexist with the urological abnormalities.^{63–66}

The most common orthopedic deformities associated with TCS include bifid spines, butterfly vertebrae, hemivertebrae, deformities of the lower extremity, and scoliosis.^{9,67,68} Unilateral or bilateral foot deformities include club feet, varus or valgus deformities, and clawing of the toes. Scoliosis is a common manifestation of OSD and TCS. Patients with progressive or atypical features with their scoliosis should be screened for OSD and TCS. Atypical scoliosis consists of left thoracic curves, progression of curve magnitude $>10^\circ$ per year, a large curve at a young age, associated pain or neurologic deficits, thoracic kyphosis $>40^\circ$, or less rotation than is expected.^{35–39} Surgical correction of scoliosis has a significantly higher risk in patients with neurologic etiologies than those with idiopathic scoliosis.⁶⁹ Many surgeons advocate neurosurgical treatment prior to any deformity corrective procedure; indications include cranial nerve deficits, cerebellar findings, motor or sensory deficits, and pain or headache.⁷⁰

KEY POINTS

- Occult spinal dysraphism (OSD) refers to a group of disorders arising as a result of incomplete formation of the midline dorsal neural, mesenchymal, and cutaneous ectodermal structures during embryogenesis.
- Spinal cord lipomas are among the most common single dysraphic lesions that often present with tethered cord syndrome.
- Dermal sinus tracts are often associated with tumors, such as dermoids, epidermoids, and teratomas, which can be found anywhere along the sinus tract.
- Cutaneous stigmata of OSD include sacral dimple/pit, capillary hemangioma, hypertrichosis (hairy patch), subcutaneous lipoma, gluteal asymmetry, or skin appendage.
- Occult spinal dysraphism and tethered cord syndrome can cause progressive neurologic, urologic, and orthopedic deterioration.

KEY REFERENCES

- Blount JP, Elton S. Spinal lipomas. *Neurosurg Focus.* 2001;10:e3.
- Lipomas of the spinal cord are very rare and cause symptoms related to mass effect and tethering of the spinal cord. Lipomas of the conus medullaris (or lipomyelomeningocele) are the most common form of fatty masses in the spine and can be divided into dorsal, caudal and transitional forms. These lesions are a manifestation of OSD and a common cause of the tethered cord syndrome.
- Kriss VM, Kriss TC, Desai NS, et al. Occult spinal dysraphism in the infant. *Clin Pediatr (Phila).* 1995;34:650-4.
- The progressive neurologic dysfunction caused by occult spinal dysraphism (OSD) can be prevented with early clinical recognition, radiographic diagnosis and neurosurgical treatment. However, detection of OSD in the infant is difficult because neurologic symptoms often are not apparent until the child becomes ambulatory. Occult spinal dysraphism can be suspected in the asymptomatic neonate when cutaneous stigmata, such as hemangiomas, hairy patches, deep and/or eccentric dimples, or subcutaneous masses, are seen over the lumbosacral spine.
- McMaster MJ. Occult intraspinal anomalies and congenital scoliosis. *J Bone Joint Surg Am.* 1984;66:588-601.
- Of 251 patients with congenital scoliosis, occult congenital intraspinal anomalies were diagnosed in 46 (18.3%). A diastematomyelia was the commonest anomaly (41 patients). Other less common anomalies included neurenteric, epidermoid and dermoid cysts; teratoma; lipofibroma; absence of nerve roots; fibrous bands; and a tight filum terminale. Intraspinal anomalies were associated with all types and sites of congenital scoliosis; by far the highest incidence (52%) occurred in association with a unilateral unsegmented bar with contralateral hemivertebrae in the lower thoracic or thoracolumbar regions.
- Pang D, Dias MS, Ahab-Barmada M. Split cord malformation: part I: A unified theory of embryogenesis for double spinal cord malformations. *Neurosurgery.* 1992;31:451-80.
- This new classification recommends the term split cord malformation (SCM) for all double spinal cords. A type I SCM consists of two hemicords, each contained within its own dural tube and separated by a dura-sheathed rigid osseocartilaginous median septum. A type II SCM consists of two hemicords housed in a single dural tube separated by a nonrigid, fibrous median septum.
- Yamada S, Iacono RP, Andrade T, et al. Pathophysiology of tethered cord syndrome. *Neurosurg Clin N Am.* 1995;6:311-23.
- Tethered cord syndrome, manifested by motor and sensory dysfunction and incontinence, is caused by excessive tension in the lumbosacral cord. The underlying mechanism is related to impairment of oxidative metabolism in this region.

Surgical and Nonsurgical Treatment of Myelomeningocele and Associated Anomalies

Jean A Ouellet, Fahad H Abduljabbar, Guillaume Raclos, Benoit Jenny, Romain Dayer

Snapshot

» Myelomeningocele (Open Spinal Dysraphism)

INTRODUCTION

Myelomeningocele is considered the most common neural tube defect (spinal dysraphism). Neural tube defects encompass a heterogeneous group of congenital anomalies of the brain and spinal cord, arising at various gestational ages. Neural tube defects are further divided into open (neural tissue exposed to the surface) and closed (skin covered) lesions. Open neural tube defects arise during the process of neurulation, between days 17 and 30 of gestation. Open spinal dysraphism includes three categories of neurulation defects: craniorachischisis (total dysraphism), anencephaly, and myelomeningocele.

The aim of this chapter is to review the contemporary treatment protocols of myelomeningocele with emphasis on its pathogenesis, prevention, prenatal and postnatal management, as well as conservative and surgical treatment options of the frequently associated spinal deformities. The more common spinal deformities found in this patient population are scoliosis, which occurs in 20–94% of patients^{1–3} depending on the level of the neural deficit and ambulatory status; kyphosis, which occurs in 8–20% of patient⁴; and final pelvic obliquity, which can be caused by supra-, intra-, or infrapelvic etiology.

MYELOMENINGOCELE (OPEN SPINAL DYSRAPHISM)

Pathogenesis

The different types of neural tube defects all represent deviations from the normal development of the spine and the

spinal cord.⁵ Basic knowledge of the normal spinal embryology allows for a better understanding of the clinical presentation, associated anomalies and therapeutic options of these lesions. The process of gastrulation, usually occurring during the third week of gestation (days 16 and 17 of gestation), converts the bilaminar embryo into a trilaminar model, consisting of the future mesoderm, ectoderm, and endoderm.⁶ The endoderm will give rise to the gut structures, the mesoderm to the striated muscles and skeleton, and the ectoderm to the skin and nervous system.⁵ Most of the current morphological and molecular knowledge of neural tube development is derived from animal studies, mainly from the *Xenopus*, chick and mouse embryos.^{7–10} Neurulation, the process of neural tube formation, is further divided into primary and secondary neurulation. During primary neurulation, notochordal induction stimulates at day 17 the overlying ectoderm layer to differentiate into the neural plate on the dorsal midline of the embryo. The neural plate will fold in upon itself to form the neural groove, a shallow midline crease just above the midline notochord visible on days 17–19. The neural groove continues to deepen with development of the neural folds laterally, which will elevate and then converge medially to close the neural tube. This closure process occurs during a 4- to 6-day period and involves the separation of the cutaneous ectoderm from the neuroectoderm (disjunction).⁸ The cranial part of the spinal cord (cranial neural tube) is the first part of the neural tube to close in a discontinuous manner through four waves of closure along the craniocaudal axis.^{11–13} The caudal neural tube closes linearly through one last wave of closure from

the point of initial contact at the cranial spinal cord to the caudal (posterior) neuropore, which closes at 25–27 days of gestation at a site located below the last visible somite at this embryologic stage. Closure of the caudal neuropore represents the last stage of primary neurulation, the process that is responsible for the formation of the majority of the spinal cord as far distal as S2. The terminal filum and probably the inferior sacral spinal cord are formed by secondary neurulation.^{8,14,15} During this last process, a mass of pluripotent cells at the caudal embryonic pole [called the caudal cell mass (CCM)] gives rise to the secondary neural tube and vertebrae caudal to S-2.

The embryogenesis of neural tube defects represents disorders of the primary neurulation. Failure of closure of the cranial neural tube (wave 2) is thought to be responsible of anencephaly. Myelomeningocele is generally thought to be caused by failure of closure of the caudal neuropore (junction of waves 4 and 5, corresponding to the junction of primary and secondary neurulation).^{8,16} This initially proposed nonclosure theory is the most widely accepted and supports the concept that neural tube defects are caused by a primary failure of neural tube closure. It probably accounts for the majority of clinically encountered cases. A second fundamental theory was secondarily developed and also supports a disorder of primary neurulation. This overdistension theory proposed that overdistension and rupture of a previously closed neural tube is responsible of neural tube defects embryogenesis. This last model may play a role in some experimental neural tube defect models.^{17,18} In addition, it was more recently proposed that some forms of complex spinal dysraphism could be the result of a failure occurring during gastrulation and leading to the formation of paired notochords, each developing into a hemicord. These double anlagen will in turn secondarily affect neurulation and induce either a hemimyelomeningocele (if neurulation is disrupted in only one hemicord) or a myelomeningocele associated with a split cord malformation (if primary neurulation fails in both hemicords).^{19,20} Finally, the embryogenesis of the Chiari II malformation, almost invariably associated with myelomeningocele, is thought to take place at a later stage of gestation. It could be linked to an abnormal development of the ventricular system because of the open neural tube defect, and this would account for the extensive constellation of anomalies seen in patients with Chiari II.^{21,22}

With the nonclosure of the neural tube, there is no disjunction of the cutaneous ectoderm from the neuroectoderm. This leaves the cutaneous layer connected laterally

to the neuroectoderm. Similarly, the associated mesoderm, including somites, develops in a lateral position forming the mesenchymal elements of the spinal canal. Consequently, at the level of the defect, the neural tissue is everted, the laterally located laminae are bifid, and the vertebral pedicles are rotated outward. Advanced rotation of the pedicles will turn the paraspinal muscles into flexors of the spine rather than extensors by displacing them anteriorly to the vertebral bodies, further aggravating a kyphosis.⁵

The neurological deficits observed in open spinal cord defect could represent the results of a two hits injury process. The first one is the malformation of the neural tube by itself and its associated structural defects. The second hit could be linked to the direct exposure of the spinal cord tissue to amniotic fluid.^{23,24} Experimental studies demonstrated the damage associated with exposure of the neural tissue to the amniotic fluid. In animal models, exposure of the spinal cord to amniotic fluid through opening of the dura was associated with neurological deficits ranging from weakness to lower limbs deformity, together with necrosis and erosion of the exposed spinal cord on histologic analysis. Using the same types of animal models, in utero closure of the defect was associated with improvement of the neurological function and of the histologic appearance.^{23,25,26}

Etiology, Epidemiology and Prevention

The exact etiology of neural tube defects is most probably intricate, and it remains currently poorly understood despite numerous advanced clinical, epidemiological and experimental studies.⁹ It is generally accepted that most cases of nonsyndromic myelomeningocele are of multifactorial origin, which is the result of complex interactions between genetic and environmental risk factors.^{27–29} Taken independently, these risk factors may play a contributive rather than a causative role to open neural tube defects.

Regarding relevant environmental factors, maternal hyperthermia, antiepileptic treatment with valproic acid during pregnancy and some nutritional deficiency or excess have been associated with a significant increase in the incidence of neural tube defects.^{7,9} Among nutritional factors, the role of folic acid is of primary importance, given its impact on prevention, and it will be discussed in great depth later in this section.³⁰

Most neural tube defects are isolated malformations, and they are potentially presenting with associated systemic congenital anomalies.³¹ These defects tend to demonstrate familial aggregation but do not follow a strict

Mendelian pattern of inheritance.^{7,9} The recurrence rate in families with an affected member is increased, with a recurrence risk for neural tube defects in siblings of patients with myelomeningocele ranging from 2% to 5%.³² The occurrence of neural tube defects among first- and second-degree relatives of an affected member was demonstrated to be significantly higher than the incidence reported in the general population. It was estimated as 3.2%, 0.5% and 0.17% in the United States for first-, second- and third-degree relatives of probands, respectively.³³

Neural tube defects may occur more rarely as part of a syndrome involving chromosomal or single-gene disorders with autosomal dominant, recessive, and sex-linked recessive inheritance patterns. In these cases, the malformation is associated with other nonrelated congenital abnormalities.³¹ These birth defects can also be associated with nongenetic syndromes.³⁴

The overall incidence of myelomeningocele is considered to be 1/1,000 live births.³¹ Many studies demonstrate some geographic and ethnic variations. The incidence of neural tube defects has clearly decreased in certain areas, partly because of prenatal diagnosis and elective terminations.^{35,36}

The primary prevention of neural tube defects today remains folic acid supplementation or fortification during the periconceptional period.³⁷ Unfortunately, anencephaly and myelomeningocele originate during the first month after gestation and many women do not even know that they are pregnant at this time. Ideally, women should have enough folic acid in their system before conception.³⁸ Periconceptional supplementation with folic acid alone or multivitamins (containing folic acid) has been associated with a 40–80% reduction in the risk of neural tube defects in intervention studies.^{39–41} In addition, the results of the observational studies and randomized clinical trial studies have also suggested that folic acid could prevent major birth defects other than those in the neural tube.^{42–44}

Many health organizations worldwide have issued recommendations for women of reproductive age to maintain a healthy diet and to take folic acid supplements. They should take 0.4 mg (400 mg) of synthetic folic acid daily in addition to consuming foods with a high concentration of folate derived from a varied diet, when planning a pregnancy.^{45,46} An increased dose (4–5 mg) of periconceptional folic acid supplementation is recommended when there is a history of neural tube defects in either a personal case or when there has been some family history.^{37,38} Despite awareness and political efforts to promote folic acid supplementation, a substantial proportion of women

of childbearing age are not implementing these recommendations. At-risk groups are those of a young age, with a lower level of education and women with unplanned pregnancies.^{37,47–55} A way to solve this problem could be to fortify foods with folic acid.⁵⁶ Some countries have opted for either voluntary or mandatory fortification of foods in addition to the promotion of folic acid supplemental use, which have shown beneficial effects.³⁷ The secondary prevention of neural tube defects relies on prenatal diagnosis, which is discussed later in this chapter.

Presentation (Including Associated Abnormalities)

Myelomeningocele is probably one of the most dramatic congenital defects compatible with life.⁵⁷ At birth, an irreversible neurological deficit of various extents depending on the level of the lesion is almost always present.³¹ The neurological function of the child has to be carefully evaluated and documented. The neurological examination is challenging usually with abnormal reflexes and occasionally spinal shock.⁵⁸ Asymmetry in neurological deficits is frequent in myelomeningocele but can be a sign of an associated spinal malformation such as diastematomyelia; hence, complete imaging of the spinal cord is mandatory.⁵ Motor denervation level is evaluated by applying a sharp stimulus to the upper extremities (or an unaffected area of the trunk) and observing the lower extremities for spontaneous motion. The level of sensory function is determined while examining the child when he is quiet or sleeping. A painful stimulus is applied from distal to proximal watching for a facial rictus or cry.⁵ The patient is usually found paraplegic at birth, since most of the defects take place at the thoracolumbar spinal level. The level of neurological deficiency moves distally as the lesion level is located more caudally. Patients with sacral lesions present often with only neurogenic bladder and subtle foot deformities.^{59–61}

The goal of the surgical primary closure of the myelomeningocele is to protect and maintain neurological function and prevent infection.⁵ Thereafter, careful monitoring of the affected child is mandatory to prevent further worsening of the neurological deficit secondary to the associated spinal deformity that can be present with myelomeningocele.³¹ These associated abnormalities include mainly Arnold-Chiari malformation, hydrocephalus and a tethered spinal cord.

The Arnold-Chiari malformation, also known as the Chiari II malformation, actually comprises multiple anomalies affecting the brain, skull and spinal cord to a varying

extent.⁶²⁻⁶⁵ The main anomaly is displacement to varying degrees of the cerebellum, pons and medulla in the cervical canal with a small posterior fossa, leading to a variable degree of compression of the brainstem despite enlarged foramen magnum and upper cervical canal.⁵ Possible associated findings include kinking of the cervicomedullary junction, brainstem nuclei changes, tectal beaking in the upper brainstem and low-lying tentorium. In addition, abnormalities of the corpus callosum, the enlargement of the thalamic massa polimicrogyria and the gray matter heterotopias may be noted in the supratentorial compartment.^{5,31} Associated respiratory and swallowing disturbances are initially observed and are the most frequent, but in most cases, they tend to be moderate and to resolve themselves spontaneously. Severe brainstem dysfunction syndrome is rare and is associated with generalized hypotonia and nasal regurgitation because of a severe swallowing disturbance, vocal cord palsy and central dyspnea. In these cases, magnetic resonance imaging (MRI) studies reveal severe Chiari II malformation with a very small posterior fossa and hydrocephalus. First line of treatment is management of hydrocephalus with a ventriculoperitoneal shunt placement, but foramen magnum decompression through suboccipital craniectomy that is associated with a laminectomy may sometimes be required.⁶¹

Most of the children with myelomeningocele present and with hydrocephalus either at birth or more frequently after the closure of the neural tube defect.⁶⁶ The contributing factors of hydrocephalus in these patients are mainly the presence of a forked and/or stenotic aqueduct of Sylvius and with the obstruction of cerebrospinal fluid (CSF) outflow from the fourth ventricle because of the small posterior fossa related to the Chiari II malformation.^{67,68} Despite these anatomic anomalies, the enlargement of the ventricles is frequently only mild to moderate, initially.⁶⁶ Surgical closure of the neural tube usually accelerates ventricular dilatation by stopping the decompression of the CSF into the myelomeningocele sac. Bulging fontanelles, altered mental status, nausea and headaches are signs of acute hydrocephalus in children.^{31,69} The preferential treatment of hydrocephalus is with the placement of a ventriculoperitoneal shunt. The ventriculoatrial shunt treatment is reserved for selected cases, whereas there seems to be no room for endoscopic third ventriculostomy in the treatment of hydrocephalus associated with myelomeningocele.^{61,70,71} There are some controversies regarding the timing for the placement of the shunt. Doing this procedure concomitantly with the closure of the neural tube

prolongs the surgical time and may increase the risk of shunt infection. Some surgeons prefer, whenever possible, to postpone shunt placement at least until 1 week after the myelomeningocele has been repaired. At birth, however, some infants present themselves with a significant hydrocephalus and they require a shunt placement at the time of neural tube defect closure.^{21,61,66,72-77} Not delaying the shunt placement when indicated is of primary importance, since hydrocephalus is one of the main coexisting pathologies responsible for morbidity and unfavorable outcome in patients with myelomeningocele.⁵⁷ Unfortunately, the rate of shunt revision is non-negligible and can be necessary in up to half of the shunted children during their first year of life. Then, however, the rate of revision decreases to approximately 10% per year.⁷⁸

After the primary repair of the neural tube defects, late neurological deterioration is mostly caused by another potentially treatable cause, the so-called "tethered cord syndrome."⁷⁹ It occurs when the spinal cord is fixed by a stiff structure and the conus medullaris is located at an abnormally low level. During normal development, the level of termination of the spinal cord gradually ascends from L4-5 at 20 weeks of gestational age, L3 at 30 weeks, to the adult level of L1-2 at 2 months of postnatal age.⁸⁰ Radiographically, the spinal cord is generally considered tethered when the conus tip is located below the lower border of the L2 vertebral body. Historically, a computed tomographic myelogram was obtained looking for a thickened filum terminale, measuring >2 mm.⁸¹ With the advent of MRI, new radiological diagnostic criteria have been put forth: location of the conus tip being below the L1-2 disc space, the diameter of the filum terminale >1 mm, or fatty thickened filum alone might be considered sufficient diagnostic criteria.³¹ Of note, children with myelomeningocele are considered to all have "tether cord"; these radiographic criteria are not diagnostic by themselves, since most of these patients will have a low-lying conus medullaris.⁸² Hence in these children, clinical findings and exam are paramount as to their management. Before assuming that new neurological deficit is from retethering, one must exclude other possible factors known to cause progressive deficit in myelomeningocele patients (Chiari II or shunt dysfunction, or hydromyelia). The most common presenting symptoms of tethered cords include weakness, deterioration in gait endurance, back pain, progressive scoliosis, progressive orthopedic deformities of the lower extremities such as cavus feet, and urinary incontinence. Magnetic resonance imaging will then help precise the

exact cause of tether and further appreciate the presence of additional associated pathologies, such as dermoid tumors, hydromyelia, and diastematomyelia.^{31,79} Early release of the tethered cord is associated with stabilization or improvement of the presenting complaints in most of the patients with myelomeningocele, so close follow-up of this patient population is indicated to promote prompt initiation when indicated.⁷⁹ The outcomes of the untethering procedure differ according to the type of presenting symptoms. The motor deficits and pain seem to improve in most of the patients, but the results are not as good for urological function. Postoperative long-term follow-up is mandatory, since symptoms of retethering will occur in up to 55% of patients.^{31,83,84} Release of a tethered cord can additionally stabilize or improve a progressive scoliosis in selected patients with myelomeningocele. Those presenting with curves $>40^\circ$ or thoracic neurological levels do not seem to improve in their curves after the untethering procedure and will ultimately require spinal fusion.^{85,86}

Latex allergy represents a major associated care issue in patients with myelomeningocele. It is an IgE-mediated reaction, which may range from mild symptoms of urticaria to severe intraoperative systemic anaphylaxis, and hence contributes to the increased risks of surgery in this patient population.⁸⁷ The prevalence of latex sensitization in patients with spina bifida, as determined by a latex skin test or an in vitro study for latex-specific IgE, has been reported to range from 25% to 51%, while clinical latex allergy had been found to be as high as 15–32%.^{88–92} A specific skin prick test for latex sensitivity appears superior to in vitro testing for latex allergy in terms of sensibility and specificity.⁹³ Age, number, types of surgical procedures (viz. urological and orthopedic nature) and the presence of a ventriculoperitoneal shunt seem to play an important role in the development of latex sensitization in children with myelomeningocele.^{88,90,91,93} It is, however, not clear whether the presence of atopy is a risk factor for latex sensitization development in children with spina bifida.^{88,90,92} The high prevalence of latex sensitization and allergy in patients with myelomeningocele justifies a primary prophylaxis by avoiding latex contacts, especially during anesthesia and surgery and also in daily life. Latex avoidance strategy has been demonstrated to be associated with safe surgical outcomes, even in patients with known clinical latex allergy.⁹⁴

Short stature is commonly encountered in spina bifida, affecting 43.5–60.5% of patients. It is more frequently noted in children with higher spinal lesions (the higher the level

of the meningocele, the greater the growth defect) and/or hydrocephalus.^{95–103} Multiple factors may be responsible for the observed short stature in patients with myelomeningocele.¹⁰¹ Lower limb contractures, spasticity and scoliosis may lead to disproportionate short stature. In addition, a significant proportion of these patients have growth hormone deficiency caused by structural brain defects or hydrocephalus.¹⁰⁴ Arm span measurement is a useful parameter in this setting. It can be easily obtained on or out of brace and is estimated to be an appropriate screening parameter together with serum insulin-like growth factor 1 and insulin-like growth factor binding protein-3 levels for the diagnosis of growth hormone deficiency in patients with myelomeningocele.^{95,103} Recombinant human growth hormone treatment has been reported to significantly increase near adult stature in growth hormone deficient children with myelomeningocele, without causing scoliosis progression. Relative obesity was also decreased with significant improvement of body mass index.¹⁰⁵ Early onset of puberty is another frequent finding.^{102,106,107} As growth hormone deficiency, this hormonal disorder seems to be of central origin and could be the consequence of damage to the hypothalamus or the pituitary gland due to increased intracranial pressure or increased mass of CSF.⁹⁹ Increased perinatal intracranial pressure has been demonstrated to strongly predict the occurrence of precocious puberty in both girls and boys with myelomeningocele.^{108,109} Treatment with gonadotropin-releasing hormone analogues can stop progression of pubertal development. Ideally, central precocious puberty in patients with spina bifida should be considered as early as possible to make possible early diagnosis and corresponding treatment.¹¹⁰ An incidence of cryptorchidism as high as 15% has also been found in male patients with myelomeningocele.¹⁰⁷

Prenatal Diagnosis and Fetal Surgery

Prenatal diagnosis has drastically affected the outcome of fetuses with myelomeningocele on many fronts. A prenatal diagnosis and formal antenatal consultations have led to the possibility of pregnancy termination, which has led to an overall decrease in the birth incidence. It also allows alterations in the mode of delivery (from vaginal to cesarean most of the times), change to earlier delivery (in cases with signs of progressive hydrocephalus), and now fetal surgical repair.¹¹¹

The usage of the different modalities available for neural tube defects prenatal detection varies worldwide

accordingly to the different national health policies and screening programs.^{112,113} Alpha fetoprotein (AFP) is a glycoprotein produced in the fetal liver, intestine and yolk sac. In embryos with an open neural tube defect and other non-neural tube lesion, the absence of the normal covering at the site of the defect allows large quantities of AFP to leak into the amniotic fluid and then into the maternal serum. The AFP serum test is performed between 15 and 22 weeks of gestation and its sensitivity ranges from 65% to 85%.¹¹³ When serum AFP is elevated, AFP amniocentesis and/or ultrasound are performed. Alpha fetoprotein amniocentesis has a non-negligible risk of complications, including miscarriage, and diagnostic accuracy can be significantly increased by amniotic fluid acetylcholinesterase determination.^{114,115} In some countries, the screening program for open neural tube defects relies only on high-quality ultrasonography.¹¹² The sensitivity of this modality has been reported to be as high as 100%.¹¹³ By defining lesion level, type, head circumference and the presence of associated anomalies, it can help predicting the postnatal outcome of affected fetuses.¹¹⁶⁻¹¹⁹ Fetal spine MRI is now used by many centers as the final noninvasive examination for prenatal evaluation of fetuses, with suspected myelomeningocele on ultrasound. Investigators reported its significant efficiency in terms of changing diagnosis, providing additional information, influencing prenatal management and predicting adverse postnatal outcomes.¹²⁰⁻¹²³

Myelomeningocele was the first nonlethal congenital anomaly to be treated with fetal surgical repair, with the first case being operated by hysterotomy in 1997.¹²⁴ The rationale for fetal surgery for myelomeningocele arose from human ultrasound observational studies and animal models of myelomeningocele with intrauterine repair, supporting the evidence that secondary neurological deficit may arise from chronic chemical and mechanical insults of the neural tissue by exposure to amniotic fluid.¹²⁵⁻¹²⁷ Both fetoscopic and open methods have been described, but open techniques seem to represent the current standard.¹¹¹ A randomized trial comparing prenatal repair before 26 weeks of gestation versus standard postnatal care recently demonstrated the benefits of fetal surgery for myelomeningocele, reducing brain stem herniation and the need for shunting, and improving motor and psychomotor outcomes at 30 months. However, the procedure was associated with maternal and fetal risks, including an increased risk of preterm delivery and uterine dehiscence at delivery.¹²⁸ The majority of children treated with fetal repair for myelomeningocele will achieve at preschool age cognitive and mobility independence, but they will

continue to necessitate significant assistance in self-care.¹²⁹ Unfortunately, neurogenic bowel and bladder management remains an important issue for patients, even after fetal myelomeningocele repair, so that they should be followed closely, similar to patients with myelomeningocele who undergo standard postnatal care.¹³⁰

Postnatal Management

Importance of Multidisciplinary Approach

Myelomeningocele is one of the most complex birth defects, affecting multiple body systems and secondarily function. This complexity needs involvement of multiple disciplines in order to deliver improved and integrated health care to patients with spina bifida. The involved specialists should include providers with expertise in the fields of neurosurgery, orthopedics, urology, general pediatrics, developmental pediatrics, physiatry, and nursing. Patients with myelomeningocele additionally often benefit from other related health care services, including nutrition, social work, physical therapy, occupational therapy (wheelchair, bracing, or seating), psychology, and family support services.^{131,132} The development of multidisciplinary clinics and teams in the 1960s was the answer to the recognition of these challenges of providing health care to children with myelomeningocele. The multidisciplinary clinic still represents today the accepted model of health care delivery to these patients.¹³³ Disbanding a multidisciplinary clinic was reported to negatively impact health care of patients with myelomeningocele, with less frequent care, loss of a coordinator of care, and a significant increase in morbidity, including amputation and nephrectomy, despite the continued availability of the same specialty care in the same location.¹³⁴ With the improvements in medical and surgical management of myelomeningocele, >75% of patients can be expected to reach their adult years. Late deterioration is frequent and rates remain lower than expected for community participation, healthy lifestyle choices, and employment and independent living. One of the current challenges is to adequately manage the adolescent with spina bifida through transition to adulthood and to promote the transfer of care to a network of adult care clinics.^{89,135}

Guiding Principle of Management of Myelomeningocele Spinal Deformities

Management of myelomeningocele spinal deformities must take into consideration each patient's individual limita-

tions, his or her expectations and his or her comorbid conditions. The location of the myelomeningocele and the resulting functional levels will dictate and significantly influence the types of treatments required to manage the spinal deformities. In addition, the underlying nature of the spinal deformity, such as congenital hemivertebra, or hyperlordosis due to a split tether cord, or even kyphoscoliosis from a simple loss of erector strength, must be identified at the onset of the treatment. All these factors will influence and dictate the nonoperative and operative treatment.

Closure of the Myelomeningocele

The initial surgical management is a critical step in the treatment of myelomeningocele and involves early closure after birth. Essential goals of surgery are preservation of neurological function, prevention of infection and avoidance of surgical complications. The discovery of a myelomeningocele is usually unexpected and careful explanation of the disease and the aim of the early treatment have to be rapidly explained to parents in order to carry out surgical treatment. Repair of the myelomeningocele involves different pre-, intra- and postoperative considerations that are equally important for surgical success.¹³⁶⁻¹³⁸ As myelomeningoceles are always associated with a Chiari II malformation, it is important to obtain a brain MRI before surgery to assess the degree of tonsillar descent and compression of the bulb and severity of hydrocephalus, which may require shunting after closure of the myelomeningocele. The difficulty of surgery and neurological prognosis depends of the anatomical variant and localization of the myelomeningocele along the neural tube.¹³⁹

Preoperative considerations: Special care has to be provided to the placode, which should be covered with humid sterile gauze to prevent desiccation and provide mechanical protection. The child should be nursed in a prone position to prevent further mechanical injury to the placode. At the time of surgery, the child is anesthetized by dedicated pediatric anesthesiologist and placed in a prone position with special care to avoid pressure point, and the placode is slightly elevated from the head to avoid continuous CSF loss. Electrophysiological monitoring even at this age is a useful tool to assess nerve root function during surgery. Microinstruments and surgical microscope are needed for use in theater. Prepping and draping are done carefully around the deformation. Skin incision is made at the junction of the normal and abnormal thin skin, allowing the development of a dissection plane between the placode

and the surrounding tissue. Extra care has to be taken to preserve vascular supply to the placode to ensure survival of the neural tissue. The free edges of the dura are exposed all around the deformation and can be held open for later reconstruction of the neural tube. An important aspect during surgery is to avoid repetitive traction on the cord, thus limiting the risk of subsequent neurological injury. Often below the placode, a thickened filum can be seen and needs to be divided. Also, all tethering bands around the placode must be freed.

An important step of the surgery is the anatomical reconstruction, which has to be done plane by plane. Usually, the malformation involves an open-ending neural tube with a central canal surrounded by the free edges of the neural tissue. One of the more critical steps of the procedure is the reconstruction of the neural canal by folding the neural placode along its long axis and held in place with a pial-to-pial closure, which is illustrated in Figure 22.1. Conceptually, this should prevent the risk of retethering. Gentle traction to the suture is critical to prevent risk of neural compression and postoperative neurological deficits. The dura is then closed with a watertight continuous running suture, once the lateral dural attachments have been freed from surrounding subcutaneous tissue (Figs. 22.2A to F). Closure of the fascia is not always achievable due to the wide opening of the spinal canal and lateral borders of the paraspinal muscles, but attempts should be made to dissect the surrounding fascia from overlying skin to obtain as much tissue for closure. Some techniques include more extensive muscle and fascial flap closure.¹⁴⁰ For skin closure, release and dissection of the subcutaneous tissue around the opening is critical to obtain as much mobile skin to close the subcutaneous tissue with 3.0 Vicryl stitches and the skin with a single suture or a running rapid 5.0 Vicryl suture. A dry dressing is used and covers the lower part with a transparent adhesive dressing just at the upper part of the sacral rim to prevent fecal contamination. The patients are nursed in a strict prone position for at least 48 hours to ensure initial healing of the wound and prevent CSF leak. Close follow-up is recommended to ensure the wounds are healing well. Moreover, these children need regular multidisciplinary follow-up.

Orthotic Treatment of Ensuing Spinal Deformities

The nonoperative management of myelomeningocele spinal deformities should be focused on function rather than on prevention of deformity progression. The loca-

Fig. 22.1: Schematic representation of a surgical view: The placode is closed with a pial to pial dissection. Adhesion between the pia and the dura need to be released to reduce the risk of retethering. The dura is closed with a watertight suture. The fascial plane on each side is released with a subcutaneous dissection to obtain enough tissue for closure.

tion of the myelomeningocele and the resulting functional levels as well as the nature of the deformity will dictate the types of treatments required to manage the spinal deformities. A congenital kyphoscoliosis associated with T11 myelomeningocele will not be managed the same as a sacral myelomeningocele presenting with a thoracic curve. Hence, in the absence of any failure of formation or segmentation of the vertebra, a low lumbar and lumbosacral myelomeningocele presenting with a thoracic or lumbar curve is treated essentially as idiopathic scoliosis with classic bracing indications. However, in the presence of a structural congenital oblique takeoff at the lumbosacral junction, leading to the idiopathic-like lumbar curve may require a hemi resection of the offending vertebra (Case 1). In patients with high lumbar myelomeningocele who are still able to be upright, treatment can consist of spinal bracing if it allows prolongation of an upright position while maintaining standing/ambulation status. Once patients are wheelchair-dependent, then seating modifications are warranted to provide lateral trunk support, as well as accommodation of any sagittal deformities such as hyperlordosis or kyphosis. For thoracic level, myelomeningocele in patients with muscle hypotonia and important thoracolumbar/lumbar curves measuring $>40^\circ$ as well as in nonambulating patients with spastic large lumbar curve, bracing is considered purely as functional bracing, as it has not been shown to alter the progressive nature of the

neuromuscular scoliosis. It can be used as sitting support.¹⁴¹ Bracing provides an external support to the spine, allowing some patients to be more functional. Its goal is to maximize functional positioning by controlling some of the spinal collapse, improving posture, and may facilitate seating. One must be vigilant as to possible worsening pulmonary function in patients with high myelomeningocele. In addition, particularly with high-level myelomeningocele, the insensate skin is at risk of breakdown and ulcers. Seating modification and choice of surface must be carefully chosen to minimize skin breakdown while providing enough support to minimize and control pelvic obliquity. Controlling and compensating hip contractures must also be taken into consideration to favorably influence the pelvis to minimize an oblique take off of the spine.

Surgical Management

Surgical management of spinal deformities in patients with myelomeningocele carries elevated morbidity and mortality rates. Common surgical complications in this patient population are deep wound infection, osteomyelitis, skin ulceration resulting from recurrent deformity or prominent implants, CSF flow dysfunction requiring shunt revision, and death. Thorough pre- and perioperative management with a multidisciplinary team approach has led to successful surgical outcome, with most patients and caregivers feeling that their spinal surgeries were beneficial to their overall well-being.^{3,142} The surgical indications for corrective spinal deformity in patients with myelomeningocele remain contentious.¹⁴² The decision to proceed with surgery must not be taken lightly in light of the overall complication rate. Severe spinal imbalance, pressure sores and loss of function¹⁴³ are the common indications to proceed with surgical management in this patient population. As their spinal deformities progress, they often decompensate in both the coronal plane and the sagittal plane, leading to significant spinal imbalance. Pronounced spinal imbalance may ultimately lead to inability to walk in the ambulatory patient, while in the wheelchair-dependent patient, it may lead to deterioration of sitting comfort and loss of sitting independence, ultimately leading to loss of activities of daily living and decrease in quality of life. Furthermore, such trunk shift and spinal imbalance can be the cause of ischial or sacral pressure sores, particularly when there is associated pelvic obliquity. These sores are indications to proceed to corrective surgeries (Case 2). The type of loss of function these

CASE 1

An 11-year-old girl presents with a progressive lumbar curve. Investigation reveals a spina bifida occulta of S2 and a hemivertebra of S1. Corrective surgery consisted of partial resection of L5 rather than S1 hemivertebra via anterior and posterior approach and fusion and instrumentation L4–pelvis. Eventual partial hardware removal second to pain. Last follow-up, patient was asymptomatic 5 years postoperatively.

patients experience can be subtle. For example, patients with a thoracic myelomeningocele and spinal imbalance typically end up supporting themselves with one of their hands, resulting in a function triplegia. Paralytic kyphotic deformities in these patients are by themselves surgical indications, as these are progressive to the rate of 4–13° per year and are resistant to all forms of conservative treatment. One last consideration for surgical management of the patients with myelomeningocele with spinal deformities is when their wheelchair can no longer be adapted to compensate for their spinal imbalance and/or their deformity.¹⁴⁴

Goals of Surgery

In all spinal deformity correction surgeries, the primary goal is to achieve spinal balance both in the coronal plane and the sagittal plane¹⁴⁵ with the least amount of risk. This cannot be overly emphasized in patients with myelomeningocele, as they classically do not have compensatory

mechanisms such as muscle tone and/or intact proprioception to rebalance themselves. Achieving balance redistributes their weight and conceptually minimizes their risk of pressure sores in both planes: Coronal imbalance 146 (Case 2) or sagittal imbalances (Case 5). It has been shown that kyphectomies Improves Sitting and Skin Problems in Patients with Myelomeningocele.”¹⁴⁶

The second objective of the surgery, which is particularly challenging in this patient population, is to achieve a solid fusion.¹⁴⁷ Achieving this solid fusion is crucial, as about half of patients with myelomeningocele with posterior spinal fusion¹⁴⁸ run the risk of developing a deep posterior spinal infection¹⁴⁹⁻¹⁵¹ with the possible necessity of hardware removal. By lacking posterior bony elements, the classic posterior lateral bone grafting technique is often inadequate. To achieve a lifelong solid fusion, it is recommended to undertake either a formal anterior approach and fusion across the segment of spinal dysraphism (Figs. 22.3A to E) or via a posterior approach, an intervertebral bone grafting technique across

CASE 2

A 16-year-old male nonambulatory with an L1 myelomeningocele, struggling for one year with a left ischial chronic skin ulcer. Patient has a severe spinopelvic deformity consisting of 100° scoliosis with 30° of pelvic obliquity compounded with hyperlumbar lordosis with thoracic kyphosis.

Patient underwent anterior thoracolumbar release, anterior interbody fusion T12 to S1 across the spinal dysraphism. Due to the hyperlordosis, the L5-S1 disc space was accessed via the body of L5 and a tibial strut graft was impacted across the disc space. Patient then had a posterior spinal instrumentation and fusion from T3 to pelvis with maximum width (MW) fixation correcting the pelvic obliquity. Across the thoracic spine, multiple Smith Peterson osteotomies were done to partially correct the thoracic kyphosis. Due to the poor midline skin, an U-shaped skin incision was done avoiding the dysraphism. (see the skin staples on postoperative film).

CASE 2

Preoperative pressure mapping shows asymmetrical weight distribution secondary to pelvic obliquity and spinal imbalance in both planes. Postoperative X-rays and pressure mapping confirm spinal balance in both coronal and sagittal planes after correction.

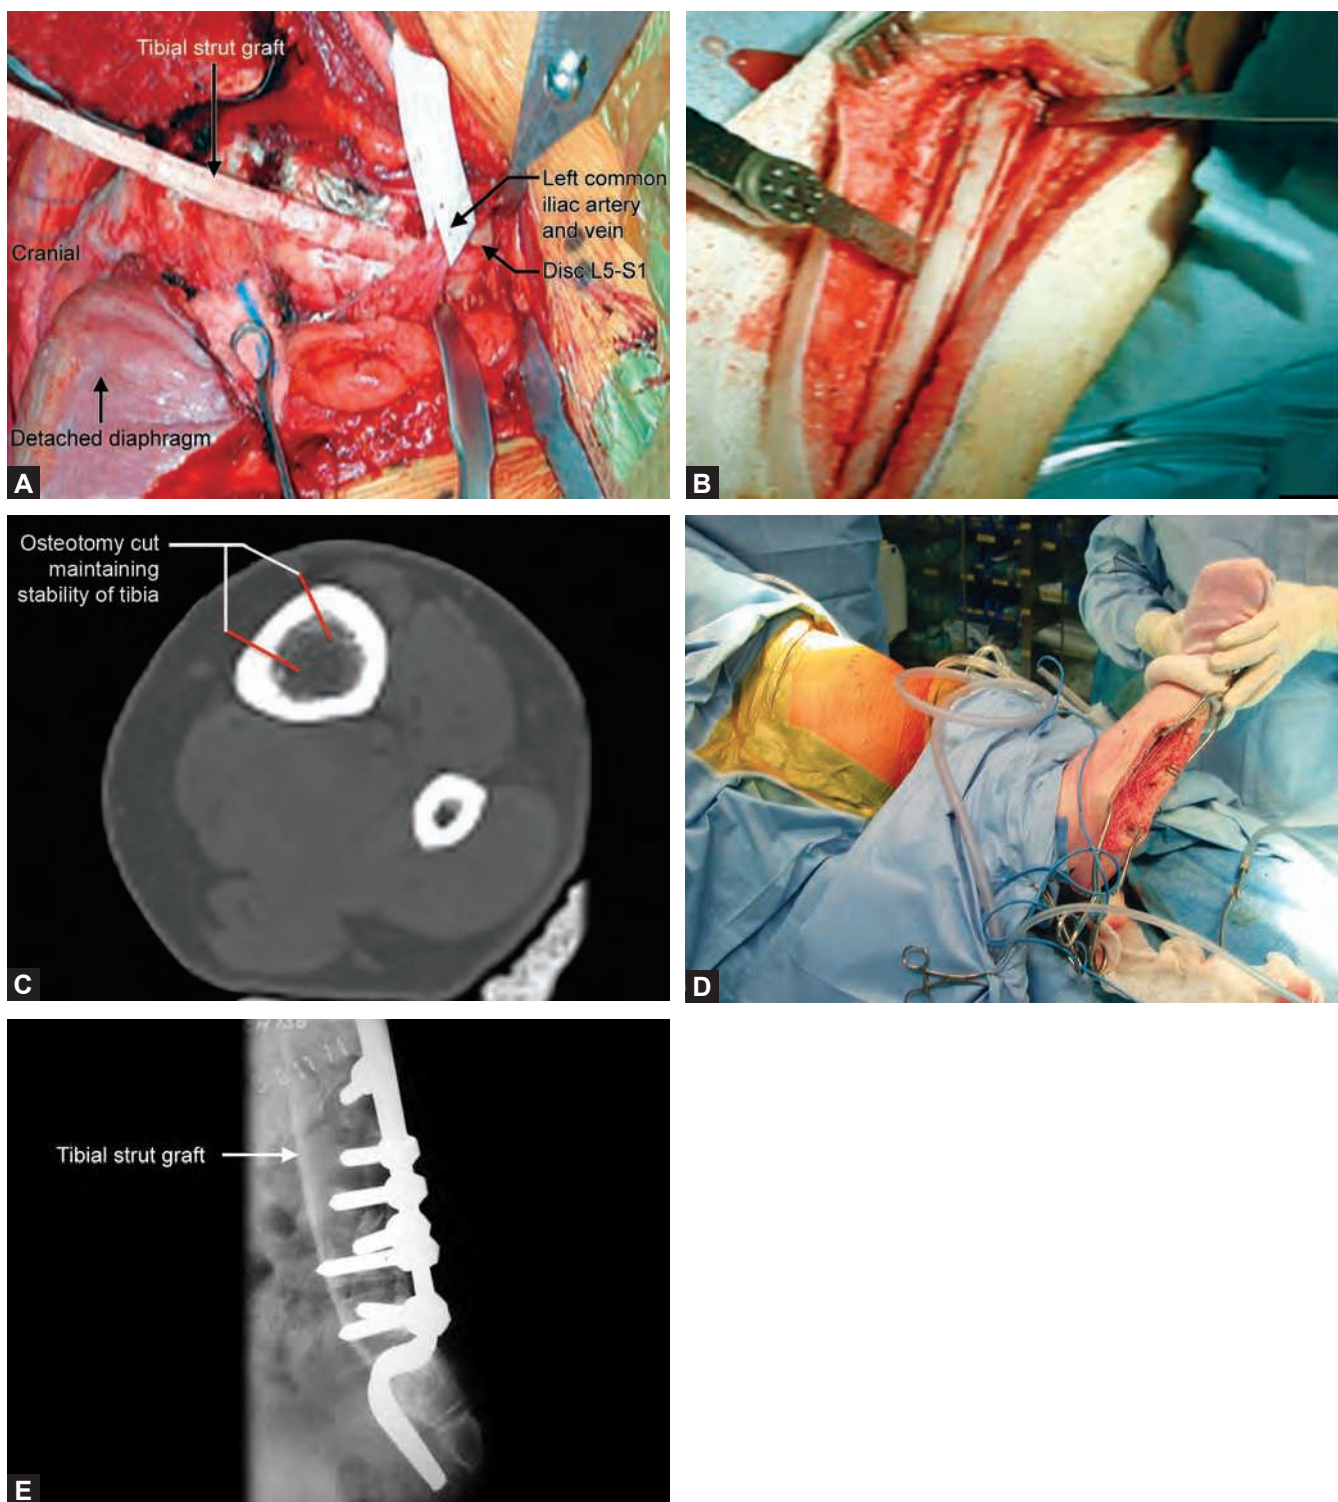

the spinal dysraphism [posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF)].¹⁵² Ligation and transection of the spinal cord and the thecal sac below the functional level of the spinal dysraphism provides great access to the anterior spinal column. Of note, such transection has been associated with altered CSF flow leading to hydrocephalus, as well as altered bladder function.¹⁵³ Patient with neurogenic bladders can remain dry as long as their urethral sphincter remains spastic/closed. Some patients who have had undergone transection of their spinal cord lose tone in their sphincter, rendering them constantly wet, which is a major problem for perineal care and hygiene. In addition, transection of the cord and ligation of the sac are associated with significant blood loss.¹ Instead of transecting the cord and ligating the dural sac, the sac can be mobilized by ligating and cutting the exiting nerve roots and retracting the dural sac on either side, providing access to the anterior column of the spine. From a biological point of view, anterior bone grafting is thought to be superior¹⁵⁴ as it remains under compression load, which stimulates bone healing, while posterior bone grafting is thought to be under tension and can remodel and even resorb.

Preoperative Workup

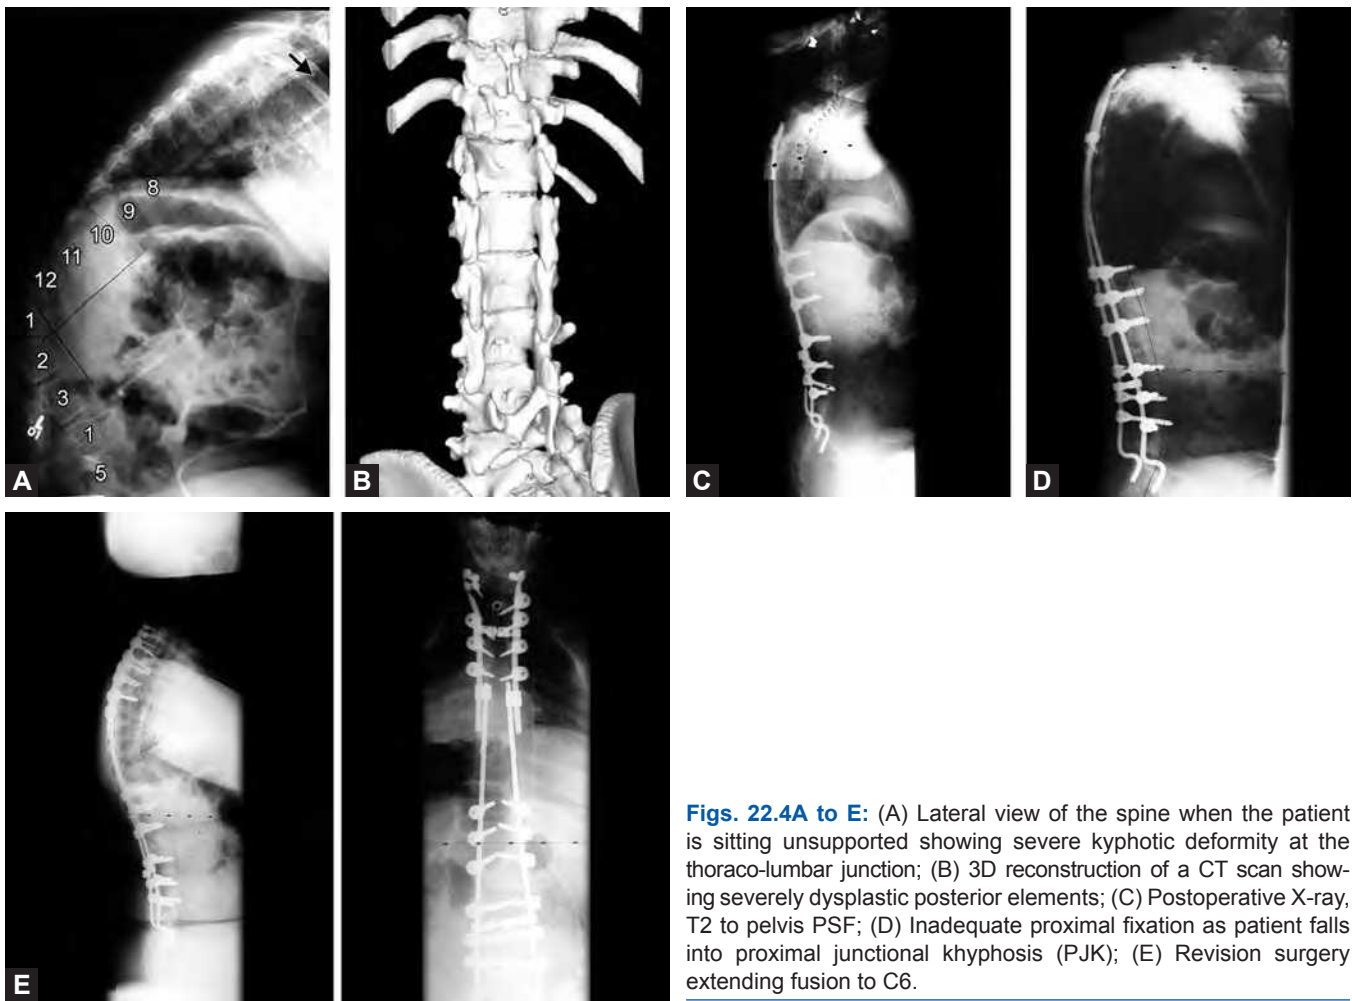

During the preoperative workup, patients' nutritional status must be assessed and optimized. Total protein, low hematocrit < 33 and albumin count can provide a clue to the patient's nutritional status.³ If deficient, then patient should be placed on nutritional supplements. As previously described, patients with myelomeningocele run a higher risk of having central apnea second to basal skull pathologies and need to be assessed for this. They often have colonization of their urinary tracts, hence these patients should receive antibiotics that covers gram negative organisms in addition to prophylactic antibiotic coverage for skin flora to minimize deep wound infections.³

Levels of Fusions

Choosing fusion levels in patients with myelomeningocele is relatively straightforward. Having no specific curves pattern dictating alternative fusion levels, one can rely on Harrington basic concept—fuse the Cobb angle, i.e. end vertebrae to end vertebrae. However, this being said,

Figs. 22.3A to E: (A) Anterior thoracoabdominal approach with diaphragm detached and mobilization of the common iliac vein and artery (Penrose) allowing for impaction of tibial autograft across the thoracolumbar and lumbosacral junctions; (B) Harvest of tibial strut graft; (C) Care must be taken to leave the "corners" of the triangular shape tibia to avoid postoperative tibial fracture; (D) Draping allowing harvesting to occur at same time of thoracoabdominal approach. (E) Postoperative X-ray showing tibial strut graft impacted in S1 up to T11.

Figs. 22.4A to E: (A) Lateral view of the spine when the patient is sitting unsupported showing severe kyphotic deformity at the thoraco-lumbar junction; (B) 3D reconstruction of a CT scan showing severely dysplastic posterior elements; (C) Postoperative X-ray, T2 to pelvis PSF; (D) Inadequate proximal fixation as patient falls into proximal junctional kyphosis (PJK); (E) Revision surgery extending fusion to C6.

in general, they tend to require additional levels of fusion as they have associated sagittal deformities such as global kyphosis and/or pelvic obliquity,¹⁵⁵ resulting in a classic neuromuscular T2 to pelvis fusion.^{4,156} Patient with pelvic obliquities $>15^\circ$ should have their fusion extended to the pelvis.¹⁵⁷ Of note, in the presence of kyphotic deformities, it is crucial that there are adequate anchor points proximal and distal to the apex of the deformity due to their poor bone quality secondary to disuse osteopenia or prolonged antiepileptic use. This poor bone quality places the implants at high risk of pullout.¹⁵⁸ Ideally, the proximal instrumented vertebra should be at the level of the first lordotic spinal segments on the lateral (Figs. 22.4A to E) above the kyphotic deformity. Selective spinal fusion¹⁵⁹ should be discouraged in this patient population, as it runs an additional risk that the nonfused segments may develop new deformities such as junctional kyphosis, particularly in the patients with hypotonic myelomeningocele. Fusing

long will avoid problematic revision surgery addressing junctional kyphosis or progressive pelvic obliquity; however, long fusion may lead to loss of function. For certain patients, their spinal deformities are actually beneficial to them. For some, having a collapsing spine lowers their center of gravity, facilitating their sitting balance. For others, having a shortened trunk facilitates their access to their perineal area for self-catheterization. In addition, a shortened spinal height can be beneficial, as their shoulders are closer to the ground and to the wheels of their wheelchair, facilitating their lifts and transfers as well as improves the power they can generate in a sitting position.¹⁶⁰ Patients' level of activity can influence the choice of fusion levels.¹⁶¹ Patients involved in paraolympic sports¹⁶² requiring thoracic motion may opt to have shorter fusion and assume the risk of requiring further surgeries to address the ensuing deformity at a later date (Case 3). The choice of fusion levels must be taken in consideration with all these factors,

CASE 3

A 15-year-old boy on state para-basketball team, L1 myelomeningocele with progressive lumbar scoliosis with problematic pelvic obliquity. Patient has normal sagittal balance, good trunk control, minimal compensatory thoracic curve.

Patient undergoes a selective lumbar fusion with extension to pelvis via paramedial incisions avoiding the midline skin breakdown and risk of CSF leaks. Three months later, he undergoes formal anterior thoracolumbar spinal fusion across all segments. Patient is now 3 years postoperative and continues to play college-level and Olympic basketball.

Figs. 22.5A to C: Modified Pedicle-vertebral body screws. (A) The entry point is at the base of the residual transverse process and needs to be significantly convergent; (B) The orientation of the screws resembles much more an anterior vertebral body screw. Right and left pedicle screws need to be slightly staggered proximal to distal, thus avoiding the opposite screw; (C) Such pedicle screw orientation allows rod positioning very lateral, hence minimizing prominence of spinal implants.

which are typically not found on X-rays. A frank discussion needs to occur with the patients and their families as to their expectation.¹⁶³ When a long fusion is undertaken, correction must lead to coronal and sagittal balance, with normalization of the sagittal alignment but moderating the urge to overcorrect the kyphosis.

Types of Spinal Fixation

The classic spinal implants for the instrumentation of the neuromuscular curves comprise sublaminar wires and L-rods.¹⁶⁴ Sublaminar wires are still being used¹⁶⁵ and remain advantageous for different reasons: minimal cost, low profile and good fixation in osteoporotic bone. Across the spinal dysraphism, as there are no laminae, the wires are passed from one foramen to the other, creating a cerclage around the pedicle stump. The overlying facets prevent the cerclage from dislodging, providing a good spinal anchor. The disadvantages of wires are the potential risk of injuring the intact neural elements (if any), tearing the dural sac during insertion, and risk of considerable epidural bleeding.¹⁶⁶ Great care must be taken as to the final placement of the twisted wires, as they may pierce the overlying skin leading to deep infections. Their tips should be twisted and tuck away under the rod or impacted into the adjacent bone. The advent of modern spinal fixation, such as pedicle screws has improved spinal stabilization for corrective surgery in neuromuscular scoliosis.¹⁶⁷ Insertion and place-

ment of “pedicle” screws in patients with myelomeningocele are obviously different than the standard pedicle screws. The main difference is the entry point, and the orientation of the residual pedicle stump is much more lateral and much more convergent. The entry point is at the base of the residual transverse process and needs to be significantly convergent. The screw heads need to be buried to avoid skin breakdown. The orientation of the screws resembles much more an anterior vertebral body screw than a pedicle screw, as the screws come across the vertebra almost in a pure coronal plane. When a right and a left pedicle screws are inserted, the entry points need to be slightly staggered proximal to distal, thus avoiding the opposite screw (Figs. 22.5A to C).

Sacral and Pelvic Fixation

Pelvic fixation¹⁶⁸ in the patient with myelomeningocele can be problematic.¹⁶⁹ Their pelvis tends to be osteoporotic and may be asymmetrically hypoplastic altering the normal anatomy. The classic spinopelvic fixation to manage pelvic obliquity associated with neuromuscular scoliosis has been the Luque-Galveston construct.^{169,170} This pelvic fixation consists of inserting the distal rods between the inner and outer tables at the level of the posterior superior iliac spine all the way across to the anterior superior iliac spine (ASIS) just above the sciatic notch. The rods need to be bent in different planes to match the lumbopelvic junction.

Additional stability of the construct can be obtained by coupling both rods with a cross link at the level of L5 and inserting bilateral S1 pedicle screws.¹⁷¹ The Unit Rod,¹⁷² a prebent U-shaped single rod, has also been shown to be an effective means of correcting the pelvic obliquity and the spinal deformity.¹⁵¹ A natural evolution of the Galveston technique was to replace the smooth rod with an iliac screw, diminishing the inherent complication of pull out and/or windshield loosening. To achieve a heightened accuracy of placement of these iliac screws, a dissection along the external table of the iliac wing can be done to establish where the sciatic notch is located using a blunt probe. Staying subperiosteal is crucial to minimize but does not exclude the risk of injuring the superior gluteal artery located in the notch.¹⁶⁷ The other technique described to improve screw placement is the use of fluoroscopic imaging. The gantry of the C-arm is oriented in the long axis of the iliac wing, creating a tear-drop-like picture allowing to confirm the ideal placement of the iliac screws.

Dunn and McCarthy described in 1989, a sacropelvic fixation specifically but not limited for patient with myelomeningocele. The S-rod fixations are prebent rods placed over the sacral ala between the transverse processes of L5 and the ileum. The S-shape portion of the rod needs to be well seated on the ala and firmly abutted anterior to the sacrum. This can be achieved by applying distraction on the rod with an L5 pedicle screw or laminar hooks. Having the rods anterior to the sacral ala and sacrum provided an added lever arm and strength to the sacropelvic fixation particularly when correcting lumbar kyphosis. Such fixation is best for the nonambulating patients with myelomeningocele, as the L5 nerve root is at risk of compression as it rests on the sacral ala. In addition, seeing the Dunn McCarthy rods are anterior to the sacrum and sacral alas, one is able to exert significant corrective force without relying on an osteoporotic pelvis.

For severe pelvic obliquity, a maximal width, “MW” segmental type of sacropelvic fixation has also been described and shown to be effective. “MW” pelvic fixation comprises a pedicle screw inserted in a Galveston fashion down the iliac wing 1 cm above the sciatic notch. As an added lever arm to correct the pelvis, a sublaminar hook pushes or pulls on an iliosacral screw described by Dubousset.

Recently, Sponseller described a sacral alar iliac screw where the entry point for this pelvic fixation lies on the sacrum, just inferior-lateral to the dorsal S1 foramen. Its trajectory is approximately 40° of lateral angulation in

the transverse plane and 40° of caudal angulation in the sagittal plane. The screw crosses the SI joint to then travel between the inner and outer tables of the iliac. The length of these screws typically ranges from 70 to 100 mm with a diameter from 7.5 to 10 mm. The advantage of such pelvic fixation is that it potentially minimizes implant prominence when compared with other fixation techniques.¹⁷³ Independent of the technique used, great care must be taken to avoid any prominent implants, as patients with myelomeningocele are excessively prone to skin breakdown due to inexistent muscle mass and insensate skin. The other challenge to manage pelvic obliquity¹⁶⁹ in this patient population is the surgeon’s ability to assess intraoperatively, if the pelvis has been leveled. Are the ischia at 90° to the spine? In certain cases, having the pelvis at 90° still does not result in balanced spine because of infrapelvic or intrapelvic asymmetry leading to uneven sitting. The advantage of using the unit rod is that if inserted correctly in the pelvis, then once the cantilever maneuver done, the pelvis has to be corrected 90° to the spine. The disadvantage is that once inserted and the correction done, if the pelvis is not 90° to the spine, then there is no segmental adjustment to be done. The advantage of the use of segmental fixation with iliac screws is that the insertion is easier; coupling to the spinal rod can be done after the iliac fixation is done and can theoretically be adjusted to attempt to obtain further correction. The downside is that seeing the coupling of the pelvic fixation to the spine fixation is not fixed at 90°, then the risk is that after the cantilever maneuver, the pelvis is still not leveled. A good technical reference for pelvic fixation is the article that Dayer et al. published in *Curr Rev Musculoskelet Med*. 2012 (Fig. 22.6).¹⁶⁸

The classic reduction maneuver for correcting pelvic obliquity consists of a cantilever maneuver¹⁷⁴ (Fig. 22.7). This entails fixing the rods distally to the pelvis at a 90° orientation to the ischial tuberosities. Then, the rods are levered across and attached to the proximal spine, thus leveling the pelvis perpendicular to the balance of the spine. Entry point in the posterior superior iliac spine (PSIS) are crucial for the unit rod and Galveston techniques as this will determine, if the pelvis will be leveled after the reduction maneuver (Fig. 22.6).

Anterior Surgery

Under certain circumstances, it may be beneficial to undertake single anterior spinal instrumentation and fusion

Fig. 22.6: Types of pelvic fixations.

Fig. 22.7: Rods are fixed to the pelvis perpendicular to the iliac crest. The rods are then cantilevered across to T2 leveling the pelvis.

in the patient with myelomeningocele. Sponseller et al recommended that in the patient with poor skin coverage and/or chronically infected posterior draining wound with

relatively supple lumbar/thoracolumbar curves $< 75^\circ$ with no kyphosis or no need to extend the fusions down to the pelvis, single anterior spinal fusion should be undertaken (Case 4).¹⁷¹ Patients with severe kyphotic deformities requiring significant corrections should also undergo anterior surgery, ideally with insertion of structural bone grafting (tibia or ribs) preventing the deformity from recurring.¹⁷⁵

When combined anterior and posterior surgery is required, the controversy continues regarding the ideal timing of the surgeries: same day versus staged.¹⁷² If staged,¹⁷⁶ how long between the two surgeries should one wait. One can also place the patient in Halo gravity traction after the anterior surgery, in the hope to obtain a gradual correction; however, the literature questions the quantifiable benefit of placing patient preoperatively in halo traction.¹⁷⁷ Current practice, which has been reflected in the literature, has been the use of multiple pedicle screws, multiple Ponte osteotomies and vertebral column resection,¹⁷⁸ instead of performing anterior release.¹⁷⁹ Intraoperative halo femoral traction has

CASE 4

A 14-year-old male, community ambulator with the use of Canadian crutches, was noted to have a progressive scoliotic deformity with minimal pelvic obliquity and no sagittal deformity. Patient is known for an extensive syringomyelia and recurrent tether cord secondary to a L3 myelomeningocele. Patient has had multiple untethering surgeries and failed syngo-plural shut secondary to recurrent posterior spinal wound infection.

The patient meets all the indications for a single anterior spinal fusion and instrumentation. A right-sided anterior approach was chosen based on the right-sided major lumbar curve, which facilitates the discectomies and instrumentation of the lumbar curve. In contrast, the thoracic curve being approached via its concavity makes the discectomies and instrumentation harder as the spine is further away and the disc spaces are collapsed down. Care must be taken while instrumenting the spine from the concavity as the canal orientation differs as to the lumbar curve so the screw trajectory must be adjusted in consequences. Patient was instrumented and fused from T4 to L4.

Single incision, double thoracotomy, with inferior extended into thoracoabdominal approach

been used to manage severe deformities and severe pelvic obliquity where differential weight is applied to the high pelvic side.¹⁸⁰ Irrespective of the type of trac-

tion, close neurological monitoring either clinically or with intraoperative spinal cord to avoid injury to the spinal cord particularly in patient with residual func-

CASE 5

- A 12-year-old male presented with a severe kyphoscoliotic deformity across the distal thoracic and lumbar spine. Patient underwent a kyphectomy to restore his ability to sit in his wheelchair.
- A closing wedge osteotomy—3 level VCR—proximal to the gibbus was done once the dural sac was mobilized to one side by ligating one set of nerve roots. Dunn McCarthy presacral rods were inserted with modified pedicle screw distally providing adequate distal fixation. Rods were then cantilevered down realigning the spine.

tion¹⁸¹ found a 50% incidence of spinal cord monitoring changes while using halo femoral traction. Complications in staged surgery have been found to be higher and some advocate same day front and back surgery.¹⁸²

Severe Rigid Spinal Deformities

Myelomeningocele patients can present with severe spinal deformities as they often have compounding factors lead-

ing to malignant curve progression. Severe kyphoscoliotic deformities, also known as hairpin deformities are often secondary to a combination of congenital malformation, tethered cords, and erector muscle subluxing anterior to the vertebral bodies. The resulting deformity is considered the end disease of spinal deformities. Such deformities are associated with significant disability and morbidity affecting patient's quality of life: recurrent pressure sores, loss of pulmonary capacity, and loss of sitting independence.¹⁸³

Depending on the overall severity and particularly the rigidity of the coronal and/or sagittal deformities, these deformities may require either multiple Smith Petersen osteotomies, asymmetrical pedicle subtraction osteotomies, versus vertebral column resections. Global kyphotic deformities are best treated with multiple osteotomies¹⁸⁴ while focal kyphotic deformities also called rigid S-shaped kyphosis¹⁸⁵ due to the associated thoracic lordosis above the lumbar kyphosis, are best treated with a kyphectomy. The complication rate for kyphectomies ranges from 20% to 85% consisting of high rate of wound breakdown, deep infections¹⁸⁶ requiring implant removal, implant failure, recurrence of deformities, and death.¹⁸⁷

Early corrective surgery, as described by Nolden et al. consists of acute correction by performing posterior resection of the ossific nuclei at one or multiple levels.¹⁸⁸

When planning a spinal column resection, one must ensure that adequate spinal anchors can be achieved above and below the vertebral column resection (VCR). It is prudent to leave some distal vertebral segments when planning a lumbar VCR, as the risk of distal fixation pull out is high. Solid pelvis fixation should be included in the fixation when performing kyphectomy. The modified Dunn McCarthy¹⁸⁹ presacral rod augmented with pedicle screws in the most distal vertebral bodies provides great distal fixation (Case 6). With such a construction, one is able to cantilever the distal segment and generate considerable force across the resected segment aligning the distal spine and pelvis with the proximal segments, thus correcting the kyphotic deformity. Proximal fixation can be sublamina wire, hooks or pedicle screws. Sharrard was the first describing such apical vertebral.¹⁹⁰

The original technique suggested transection of the dural sac and spinal cord. Others have described to spare the sac by transecting the roots and mobilizing the cord.¹⁹¹ When performing a kyphectomy, the vertebrae contributing to the hairpin deformities are identified and need to be circumferentially dissected. Initiating this extraperiosteal circumferential dissection from both sides at the disc level will minimize the risk of inadvertent laceration/avulsion

of the segmental arteries. The segmental arteries are found at the mid-level of the vertebral bodies,¹⁹² and need to be ligated/cauterized in a controlled fashion. Further, blunt dissection above and below the disc and across the vertebra by detaching the psoas muscle allows complete isolation of the spine. Blunt retractors are placed for either side of the spine, ensuring the great vessel and the peritoneum are protected and reflected anteriorly.¹⁹³ Greater the kyphosis, easier is this dissection as the abdominal content falls forward in the prone position. Once the planed resected vertebrae have been circumferentially dissected, the dural sac has been transected or mobilized and blunt retractors are protecting the great vessels. The vertebra can be cut with an oscillating or Gigli saw at a bony surface, thus providing good bony apposition. As one does this, one encounters significant blood loss, and it persists until the two ends of the vertebrectomy have been approximated. Having the rods already anchored distally prior to resection saves time and allows for controlled reduction. That is why, the spinal anchorage points must be already in place and that the actual kyphectomy is done last (Case 5).

Young Myelomeningocele Patient

Young patient with progressive spinal deformities and with significant growth poses an even greater challenge. The timing of managing this severe sagittal spinal deformity has been advocated at all ages. In the newborn and young infant, one can achieve significant correction by performing posterior resection of the ossific nuclei at one or multiple levels.¹⁹⁴

However, initiating a surgical management in these young patients with progressive spinal deformities and with significant growth poses an even greater challenge.

Growth, sparing procedures, such as growing rods and VEPTR carry by themselves a high complication rate centered on wound issues and spinal anchor failures, both of which myelomeningocele patients are prone to develop. Smith et al¹⁹⁵ have advocated the management of early myelomeningocele kyphotic spinal deformity using rib to pelvic growth-sparing fixation (Case 6). Conceptually, this technique is advantageous as it maintains spinal length and growth. Additional advantage of using rib-to-pelvis instrumentation in the incisions are well away from the midline spinal dysraphism area minimizing the risk of infection or skin breakdown. Initial results have been promising in the nonambulating patients. In the ambulating patients, they have noted that over time, the repeated lengthening

CASE 6**A. Preoperative**

- A 6-year-old patient with L1 myelomeningocele, central apnea secondary to severe Arnold-Chiari requiring a tracheostomy. Presented with progressive kyphoscoliosis and pelvic obliquity.

B. Postoperative

- Patient underwent posterior spinal instrumentation with distal S rod pelvic fixation and modified pedicle screw to counteract kyphotic forces and altered myelomeningocele anatomy, while proximal fixation consisted of Luque trolley-type gliding fixation for growth.
- Lumbar interbody fusion was undertaken via PLIF type approach with multiple discectomies and cancellous bone grafting.
- Correction maneuver consisted of obtaining distal fixation with S rods and lumbar screws and cantilevering rods down and across correcting both coronal and sagittal deformities

C. Postoperative (3 years)

- Three years postoperative patient's correction remain acceptable with evidence of spinal growth with sublaminar wire traveling proximally. However, patient is developing proximal junctional kyphosis. In addition, pelvic S rods are shifting along pelvic rim. Both of these complications may require revision surgery as some point to prevent progressive deformity.

CASE 7

A 5-year-old girl with severe lumbar kyphosis underwent growth sparing spinal surgery with insertion of bilateral rib-to-pelvis fixation—VEPTR. Gibbous was obviously flexible allowing for significant correction, and maintenance of spinal height.

is kyphogenic in nature and alters the pelvic parameters rendering their gait awkward. This technique is promising. However long-term results are still lacking. Other techniques¹⁹⁶ can be considered for the very young myelomeningocele patients such as hybrid constructs where the primary lumbar curve and the pelvic obliquity are corrected and fused while the thoracic curve is not fused but only instrumented using a Luque trolley type fixation allowing ongoing growth and development of the chest wall and thoracic spine¹⁹⁷ (Case 7).

In summary, managing spinal deformities in the patient with myelomeningocele requires a good knowledge of spinal anatomy, meticulous attention to skin-handling and vigilant aseptic techniques. Preoperative planning is essential, and focusing on skin incision, type of fixation, and anterior column fusion minimizes perioperative complications. Despite good perioperative management, complications remain high and are best managed in a multi-disciplinary fashion.

INTRODUCTION

Chiari malformations are a collection of posterior cranial fossa abnormalities due to abnormalities in rhombencephalon descent and cerebellar ectopia. Although Hans Chiari was not the first person to describe these hindbrain abnormalities, his report in 1891 originally classified two types of these rhombencephalic anomalies. Subsequent work over the last century has further distinguished more subtypes. The two most common and major subtypes are type I and type II malformations, which are believed to be pathologically distinct disorders.

Chiari type I malformation (CIM) is most common and is defined as the herniation of the cerebellar tonsils >5 mm below the foramen magnum, with no associated brainstem herniation or myelodysplasia. Cervical syringomyelia is the most common associated finding with this subtype. In contrast, Chiari type II malformation is always associated with myelodysplasia and involves herniation of the brainstem and vermis, in addition to the cerebellar tonsils, through the foramen magnum. Syringomyelia is also commonly seen with Chiari type II malformation.

Chiari type III, the rarest and most severe form of these disorders, involves an occipital or high cervical encephalocele that contains herniated cerebellar or brainstem tissue. Chiari type IV, which involves hypoplasia or aplasia

of the cerebellum, has a relatively normal posterior fossa size and no cerebellar herniation. Recently, there have been descriptions of new variants such as “Chiari 0” malformation, which is syringomyelia without cerebellar tonsil herniation, and “Chiari 1.5” malformation, which is Chiari I and additional brainstem herniation without myelodysplasia.¹⁻³ This chapter will focus primarily on the pathophysiology of CIM given its prevalence and onset in adolescence and adulthood.

DIAGNOSIS

Radiographically, CIM is defined as herniation of the cerebellar tonsils of 5 mm or greater below the foramen magnum, in the absence of any intracranial lesion or malformation that may lead to increased intracranial pressure. Recent advances in imaging have revolutionized the diagnosis of Chiari malformation. In a study of 200 normal patients and 25 patients diagnosed with CIM, Barkovich et al. concluded that tonsillar herniation of <2 mm is likely of little clinical significance in the absence of syringomyelia.⁴ They also demonstrated that 14% of normal patients had tonsils extending slightly below the foramen magnum and 1 in 200 normal patients had tonsils 5 mm or below the foramen magnum by magnetic resonance imaging (MRI).

Aboulezz et al., in a study reviewing >800 MRI examinations, found that up to 3 mm of tonsillar herniation is

Fig. 23.1: Sagittal T2 magnetic resonance imaging demonstrating Chiari I malformation.

Fig. 23.2: Axial T2 magnetic resonance imaging demonstrating crowding of the cerebellar tonsils at the level of the foramen magnum.

normal but may be pathologic when exceeding 5 mm, with borderline cases between 3–5 mm.⁵ However, the authors note mild ectopia between 3–5 mm should be considered significant, if there are neurological symptoms, syringomyelia, cervicomedullary kinking, or peglike appearance of the cerebellar tonsils.⁶ No significant correlation has been found between the severity of symptoms and the extent of herniation.¹ Importantly, it is notable to consider that cerebellar tonsils ascend with age, such that 6 mm herniation is considered pathologic in the first decade of life (Figs. 23.1 and 23.2).⁶

Mechanisms Causing Chiari Malformation

Several mechanisms leading to cerebellar tonsil herniation in CIM have been proposed, including cranial constriction, spinal cord tethering, cranial settling, intracranial hypertension and intraspinal hypotension.⁷ Cranial constriction is seen in patients with craniosynostosis, achondroplasia, acromegaly, and Paget's disease and is associated with a smaller area of the foramen magnum outlet. Spinal cord tethering is seen in those with Chiari type II malformation and leads to an abnormally enlarged foramen magnum. Spinal cord tethering may be more rarely seen with a fatty filum terminale in cases without spinal dysraphism.

The remaining three mechanisms of cerebellar herniation do not have an abnormal posterior cranial fossa dimension and likely represent distinct etiologies. Cranial settling is seen in patients with hereditary disorders of connective tissue or post-traumatic patients with

occipitoatlantoaxial joint instability. Intracranial hypertension is found in patients with hydrocephalus, posterior fossa masses, subdural hematomas, or other intracranial mass lesions. Intraspinal hypotension is seen in patients with a prolonged lumboperitoneal shunt, cerebrospinal fluid (CSF) leaks, or dural ectasias.^{1,7}

CLINICAL PRESENTATION

The clinical presentation of patients with CIM varies widely, from subtle headache to myelopathy and symptoms of brainstem compression.² Occipital headache and upper cervical pain induced by laughing, sneezing, or coughing is the most common presentation.⁸ In addition, more than half of patients also have some ophthalmologic symptoms (blurry vision, nystagmus, and visual field deficits) and otologic disturbances (tinnitus, hearing loss and vertigo).⁹

Other symptoms resulting from myelopathy and brainstem compression include motor and sensory deficits, hyper-reflexia, ataxia, lower cranial nerve deficits, and loss of pain and temperature sensation. Myelopathy can result from direct cord compression or syringomyelia, with the syrinx most commonly found in the cervical area. Without treatment, a syrinx can lead to progressive myelopathy with sensory and motor functional loss, and can produce progressive spinal deformity.¹⁰

Young children <3 years old often present with lower cranial nerve dysfunction that leads to poor feeding, dysphagia, diminished gag reflex and vocal cord paralysis.¹¹ Sleep apnea due to airway collapse may lead to sudden

death. Reviewing MRI studies, Trigylidas et al. found a significant reduction in the volume of the posterior cranial fossa in symptomatic Chiari type I patients compared to asymptomatic patients aged 10–18 years. No difference was found in patients <10 years of age however.¹² These results underline the importance of monitoring asymptomatic patients for the development of symptoms later in life.

■ SYRINGOMYELIA

In symptomatic Chiari type I patients, syringomyelia can be found in 40–85% of the times, with this prevalence being smaller in asymptomatic patients.^{1,13} Communicating syrinxes were found in association with hydrocephalus and in conditions, such as Chiari type II and Dandy-Walker malformation. Noncommunicating syrinxes were seen predominantly in adults and in disorders that affect CSF dynamics such as CIM, basilar impression, and arachnoiditis. These isolated syrinxes are cavities that dissect paracentrally into the spinal cord and are lined with glial scar and myelomalacia.

■ PATHOGENESIS

Chiari type I malformations are congenital forms of cerebellar herniation at least 5 mm below the level of the foramen magnum. Many hypotheses have been proposed about their pathogenesis. Some leading theories include hindbrain dysgenesis, developmental arrest theory, caudal retraction theory, the Gardner's hydrodynamic theory, small posterior fossa theory, and lack of embryologic ventricular distension theory.

Chiari type I and type II malformations most likely share different pathophysiologic origins. However, the impaired CSF flow across the craniocervical junction, seen in both CIM and Chiari type II malformation, probably leads to the development of syringomyelia.

Chiari I Malformations

There are both congenital and acquired causes for CIM. In regard to congenital CIMs, mesodermal defects can lead to a small posterior fossa. A small posterior fossa can cause compression of the neural elements and herniation through the foramen magnum, which can lead to subsequent alteration of CSF flow. Aberrant CSF flow may lead to the symptoms seen in CIM. Furthermore, CIM is often seen with other mesodermal defects, such as other spine, skull, somatic, and craniofacial abnormalities. Abnormalities of the upper cervical spine include hypermobility of

the craniovertebral junction, Klippel-Feil syndrome, occipitalization of the atlas, and anterior indentation of the foramen magnum (either basilar invagination or retroversion of the odontoid process). Chiari I malformation is also strongly associated with craniosynostosis, especially the syndromic, multisuture, and lambdoid synostosis types. Certain types of synostosis can either decrease the volume of the posterior fossa or cause elevated intracranial pressure, facilitating the herniation of posterior fossa contents.²

Besides mesodermal defects, there can be acquired causes of CIM. The presence of a craniospinal pressure gradient across the foramen magnum can promote formation of CIM. For example, if the spinal compartment has a relative negative pressure compared to the intracranial compartment, this can cause a “sump effect” upon the cerebellar tonsils into the foramen magnum. Iatrogenic means, such as repetitive lumbar punctures, lumbar drainage, chronic CSF leaks, and lumboperitoneal shunting, can cause acquired CIM.²

Syringomyelia

A number of theories have been proposed to explain the development of syringomyelia in CIM. Gardner's “hydrostatic theory” suggests that retained communication of the central canal with the fourth ventricle, secondary to delayed embryonic opening of the fourth ventricle's outlets, leads to hydrodynamic stresses in embryonal and early fetal life with resultant syringomyelia.¹⁴

Williams' “craniospinal pressure dissociation” hypothesis is also predicated on a persistent connection between the fourth ventricle and the central canal. This theory notes that there is difficulty in rapidly equilibrating CSF pressure wave seen during valsalva. During this delay, there is a vector of force out of the intracranial cavity, and the prolonged pressure differential results in downward migration of the cerebellar tonsils, resulting in the obstruction of CSF flow between the posterior fossa and the cervical subarachnoid space. This leads to continued fluid flow into the central canal from the fourth ventricle.¹⁵

In contrast, with the knowledge that there is rarely a communication between the ventricular system and a syrinx, using phase contrast MRI, Oldfield found that the cerebellar tonsils in Chiari type I patients partially occlude the subarachnoid space at the foramen magnum. The increased pressure in the subarachnoid space leads to diffusion of fluid through the perivascular space of the spinal cord and formation of a syrinx. Authors have noted this theory fails to account for the higher pressure found

in the syrinx than the subarachnoid space, the different composition of syrinx fluid than that of CSF, and the presence of extensive gliosis and wall thickening found in the syrinx.¹⁶⁻¹⁸

More recently, studies in animal models and fluid dynamics imaging have suggested the role of arterial pulsation in syrinx formation, as Chiari type I patients were found to have a prolonged systolic flow pattern, leading to CSF penetration into the spinal cord.^{19,20} Combining these different ideas, Levine proposed a unified hypothesis where obstruction of CSF flow at the foramen magnum leads to changes in the transmural pressure of the vessels above and below the blockage. While capillaries and veins above the blockage dilate, those below the blockage collapse, resulting in mechanical compression of the spinal cord. This chronic stress on the spinal cord leads to parenchymal injury, breakdown of the blood-spinal cord barrier, and accumulation of fluid in the region of the damaged spinal cord, ultimately leading to syrinx formation.

TREATMENT

Appropriate patient selection for surgical decompression can be challenging, and surgical indications vary from surgeon to surgeon. As patients respond best when operated on within 2 years of onset of symptoms, early surgery is recommended for symptomatic patients. Asymptomatic patients should be followed in clinic and operated upon, if the patient becomes symptomatic, although many surgeons consider radiographic development of a syrinx to be adequate indication for operative intervention.

In a patient suspected of having CIM, the patient should undergo an MRI of the posterior fossa as well as the entire cervical spine to screen for a syrinx. Long-tract signs on physical examination without evidence of cervical syrinx should also warrant MRI of the thoracic and lumbar spine. Brain imaging should be obtained to rule out hydrocephalus.

The presence of a syrinx suggests that there are pathologic forces upon the spinal cord. A small, asymptomatic syrinx may be followed with serial follow-up and imaging. In patients without a syrinx and who are minimally symptomatic (mild headache), observation and clinical follow-up may be appropriate. Surgery can be deferred until symptoms progress or headaches become refractory to conservative treatment. Patients with severe headaches or objective neurologic findings should receive earlier surgical intervention.

In patients with concomitant hydrocephalus or elevated intracranial pressures, the hydrocephalus should be treated first. Ventriculoperitoneal shunting or third ventriculostomy are options to treat the hydrocephalus. If symptoms persist or if an associated syrinx remains unchanged after observation, even after shunting or third ventriculostomy, then a posterior fossa decompression should be considered.

Chiari Decompression

The aim of the surgery is to restore the natural CSF dynamic flow from the fourth ventricle to the subarachnoid space and decompress the brainstem. There are currently no known nonsurgical means of treatment for symptomatic CIM.

The patient is placed in a prone position on chest rolls with the head flexed and secured in a Mayfield headholder. The neck is flexed to open the interspace between the occiput and posterior arch of C1. The shoulders can be retracted inferiorly with tape (Fig. 23.3).

A midline incision is made from theinion to the level of the C2 spinous process. Staying midline separates the soft tissue and muscles along an avascular plane (Fig. 23.4).

The foramen magnum and the C1 posterior arch are exposed the width of the cervical dura. The bone above the foramen magnum is removed, generally approximately 5 cm high by approximately 5 cm wide, although smaller craniectomies are favored by some surgeons. Overly aggressive resection of the occipital bone can lead to

Fig. 23.3: Patient positioning. The patient is positioned prone for a midline posterior fossa approach. The patient's head is translated posteriorly and flexed. Flexing the head opens the foramen magnum-C1 interval. The patient is placed on chest rolls to prevent an increase in intrathoracic pressure. *Source:* Taken from *Core Techniques in Operative Neurosurgery* by Jandial.

Fig. 23.4: Incision for a Chiari malformation decompression. A midline incision is made from the inion down to the level of the cervical lamina one level below the lowest extent of the cerebellar tonsils.

Source: Taken from Core Techniques in Operative Neurosurgery by Jandial.

cerebellar sag and herniation. A C1 laminectomy is performed. Usually, a C2 laminectomy is unnecessary; maintaining the muscle attachments and lamina of C2 minimizes postoperative pain (Fig. 23.5).

The dura is then opened in a Y-shaped fashion. The tonsils can gently separated to inspect for veils or adhesions covering the outlets of the fourth ventricle. Some surgeons choose to use bipolar cautery to shrink the ton-

Source: Taken from Atlas of Neurosurgery by Meyer.

sillar tips or to perform lysis of subarachnoid adhesions to restore CSF flow. Many surgeons perform only opening of the dura, and try to remain extra-arachnoid in placing a dural graft, with the rationale that restoration of CSF hydrodynamics may be accomplished simply by allowing for greater expansion of basal arachnoid cisterns (Fig. 23.6).

A dural graft is then sewn to provide a more spacious posterior fossa. Pericranium or fascia lata may be harvested for the graft, or artificial dural graft may be used (Figs. 23.7 and 23.8).

Fig. 23.8: Sagittal magnetic resonance imaging demonstrating decompression of posterior fossa and foramen magnum.

COMPLICATIONS

Chiari decompression is a significant cranial procedure and is not without risk. Risks include CSF leak, pseudo-meningocele, herniation of cerebellar hemispheres, vascular injury (especially the posterior inferior cerebellar arteries), and meningitis. Although occipital-cervical instability is a potential complication, cervical kyphosis or postoperative instability is rarely seen. Cerebrospinal fluid leaks developing in the postoperative period may be indicative of previously unappreciated hydrocephalus, which may require treatment via ventriculoperitoneal shunting procedures.

In one study of 71 patients, one patient died from sleep apnea, and respiratory depression, the most commonly seen complication, was seen in 10 patients.²¹ In another series of 130 patients, acute postoperative hydrocephalus due to infratentorial hygroma was seen in 2 patients, and temporary external ventricular drainage was required.²² In this same series, a retroflexed odontoid process was seen in only one patient who required a transoral odontoidectomy. Posterior fossa craniectomies that extend too laterally have the risk of “cerebellar slump”, where the cerebellum herniates through the craniectomy defect. This may cause headaches that are different in quality than typical Chiari headaches, but may be remedied with a cranioplasty to support the cerebellum into correct position.

RESULTS AND PROGNOSIS

The main goal of surgery is to halt the progression of symptoms. Patients with preoperative complaints of pain may

respond well to surgery, although predicting outcomes with regard to relief of headache symptoms can prove difficult. Furthermore, syrinxes should decrease over months after surgery. Motor weakness is less responsive to surgery, especially if muscular atrophy is already present.²³ Factors that correlate to a worse outcome are the presence of atrophy, ataxia, scoliosis, and symptoms lasting longer than 2 years.²³

Poor clinical resolution of CIM may be due to inadequate decompression. In patients who initially improve with decompression and then worsen at a latter time, return of CSF flow compromise may have developed. These patients will usually respond to repeat decompression; some may also consider resection of portions of the cerebellar tonsils. In patients with persistent syrinxes, unresponsive to adequate surgical decompression, a syringopleural or syringoperitoneal shunt may be considered.

KEY POINTS

- Chiari malformation involves disruption of normal CSF flow through the foramen magnum. Occipital and upper cervical pain, induced by laughing, sneezing, or coughing, is the most common presentation. Other symptoms resulting from myelopathy and brainstem compression include motor and sensory deficits, hyper-reflexia, ataxia, lower cranial nerve deficits, and loss of pain and temperature sensation. Syringomyelia is also commonly seen in CIM.
- Treatment of CIM, when indicated, is surgical. The purpose of surgery is to enlarge the posterior fossa, restore normal CSF outflow from the fourth ventricle, and relieve brainstem compression.
- After decompressive surgery, there is generally resolution of Chiari malformation symptoms as well as resolution of syrinxes, if they are present.
- Complications of surgery are usually minimal; however, there is always a risk of CSF leak, pseudomeningocele, damage to neural or vascular structures, meningitis, and respiratory depression.
- Treatment of a syrinx, when not the result of cerebellar tonsil herniation, includes shunting of the syrinx into the adjacent subarachnoid space, peritoneum, or pleura.

INTRODUCTION

Osteogenesis imperfecta (OI) is a rare but serious heritable disorder of collagen synthesis with variable and wide-ranging skeletal manifestations. These classically include osteoporosis with increased bone fragility, ligamentous laxity, short stature or dwarfism, and deformities of the spine, pelvis, and long bones. Additional characteristic nonorthopedic manifestations, such as blue sclerae, hearing loss, and defects of dentinogenesis, may be present. Numerous historic accounts of familial “brittle bone disease” exist, with the first scientific description by in the doctoral thesis of Olof Jakob Ekman in 1788.¹ The disease terminology was inconsistent until the first use of the term “osteogenesis imperfecta” by Willem Vrolik.¹ Recent advances have allowed for more detailed subclassification based upon the molecular pathophysiology of the disease variants; however, overall prevalence is estimated at approximately 16 cases per million and is evenly distributed across ethnic groups.²

The genetics and specific phenotypic subtypes of OI were first subclassified by Sillence et al.³ Incidence ranges from 1 to 2 per 100,000 births for severely deforming autosomal recessive type III to 3 to 5 per 100,000 births each for both mild autosomal dominant type I and severe autosomal recessive type II. While historically lethal in the perinatal period, survival into the perinatal period with type II disease is now possible with modern treatment.

The incidence of the autosomal dominant type IV form is unknown. Numerous abnormalities of the *COL1A1* and *COL1A2* genes have subsequently been identified, which result in quantitative or qualitative abnormalities in synthesis of type I procollagen.^{4–6} Types I and IV are subclassified into A and B variants based on the absence or presence of associated dentinogenesis imperfecta. The four initial types described by Sillence et al. have been expanded upon by Rauch and Glorieux et al., who described types V, VI, and VII, which produce OI-like disease states without evidence of type I collagen abnormality. Instead, other etiologies have been proposed, such as defects in remodeling capacity and osteoid mineralization.^{7–9} In addition, Cabral et al. have described an autosomal recessive type VIII caused by a defect in cartilage-associated protein, which participates in the process of collagen hydroxylation.¹⁰

Multiple manifestations of OI have been described affecting the cervical, thoracic, and lumbar spine (Figs. 24.1A to E). Across all subtypes, approximately 60% of subjects with OI exhibit some form of spinal deformity, ranging from nearly 90% in severe congenital forms to 10–40% in the less severe forms previously described as mild tarda forms.¹¹ Abnormalities of the craniocervical junction (Figs. 24.2A to D), thoracic kyphoscoliosis, lumbar hyperlordosis, and spondylolisthesis have been observed. Kyphoscoliosis is the most common finding, typically associated with multiple vertebral compression fractures and/or rib fractures, and may result significant thoracic deformity. The vertebral

Figs. 24.1A to E: Spinal manifestations of osteogenesis imperfecta.

bodies are often flat or biconcave due to accumulated osteoporotic microfractures. The resulting spinal deformity may result in significant morbidity due to impaired respiratory function, delayed motor milestones, and poor quality of life.^{12,13}

DIAGNOSIS AND MEDICAL THERAPY

While tissue typing and molecular and genetic testing have become increasingly widespread, the diagnosis of OI remains primarily clinical. The combination of multiple fractures in the setting of minimal trauma, along with characteristic osseous and nonosseous deformities as previously described with supporting radiographic evidence, may be highly suggestive of the diagnosis. Advances in fetal ultrasound have made it possible to prenatally iden-

tify structural features of OI but is not completely accurate in predicting the diagnosis or severity of the disorder.¹⁴ Postnatally, molecular studies may be performed from culture of skin fibroblasts, which confirm a defect in type I collagen synthesis in approximately 90% of patients.¹⁵ In children with less severe or obvious clinical phenotypes, dual-energy X-ray absorptiometry scanning may reveal significant reductions in bone mineral density compared to age-matched controls.¹⁶ Other conditions in the differential diagnosis of OI include fibrous dysplasia, hematologic malignancies, hypophosphatasia, and idiopathic juvenile osteoporosis. In addition, nonaccidental trauma must be excluded in any case where multiple fractures are present in various states of healing.

While numerous surgical interventions have been described for acute fracture management, early systemic

medical therapy for OI is essential to maximize bone mineral density and reduce fracture risk. A multidisciplinary team effort is required to optimize diet, vitamin D and calcium intake, as well as appropriate guided activities to ensure safe but maximal psychomotor development. Bisphosphonate medications have been shown to increase cortical thickness and trabecular bone volume via reduction of osteoclast activity, and are a mainstay of pharmacologic treatment.^{17,18} When used in infancy for treatment of severe cases, bisphosphonates have shown short-term safety and efficacy in maintaining mobility and prevention of secondary deformities.^{19,20} Bisphosphonates have also resulted in improved vertebral height and development in children with compressed vertebral bodies.²¹ Despite its benefits for prophylaxis, the potential for impaired fracture or osteotomy healing and decreased rate of remodeling with ongoing use of bisphosphonates must be considered in the setting of acute fracture or surgical intervention.¹⁸

■ PERIOPERATIVE CONSIDERATIONS

Despite optimal medical management, patients with OI often require surgical intervention for acute injuries or progressive deformity. It is imperative that the surgeon and anesthesiologist consider the systemic physiologic effects of the disease process in the perioperative setting. Handling of the anesthetized patient with OI requires additional vigilance on the part of the operating room staff to prevent inadvertent injury.²² The treating surgeon should ensure that entire surgical team is aware of the risks of extremity fractures during positioning, and should be present during positioning and transferring to and from the operating room table. Stabilization of the cervical spine by the surgeon during intubation and positioning of the patient is important to prevent cervical injuries. Positioning of the patient on the operating room table may also be challenging due to thoracic or pelvic malformations, and/or stiffness or malunion of the extremities. Standard tables may not be appropriate, and proper planning as well as creativity is necessary to optimize safe positioning while respecting the general rules that apply to all spinal procedures (Figs. 24.3A to F). Postoperatively, with the collaboration of the parents, the nursing team must also be aware of the increased potential for injury. Abnormal facial and cranial morphology may result in difficulties with airway management, as does the increased risk of dental injury.²³ Thoracic deformity may result in compromised respiratory function. While under general anesthesia, a tendency toward hyperthermia with diaphoresis has been reported

in patients with OI,^{24,25} though a recent series reported similar intraoperative temperature and end-tidal carbon dioxide measurements between groups of patients with and without OI.²⁶ In the authors' experience at large centers treating many hundreds of patients with OI, there is no evidence that patients with OI have an increased risk of malignant hyperthermia, and the trend toward mildly increased baseline body temperature should be recognized with care taken to avoid overwarming.²⁶ Of particular interest to the surgical team is a variable level of coagulopathy that has been reported in with OI, which may result in greater-than-anticipated surgical blood loss.²⁷⁻²⁹ Approximately two-thirds of patients will report easy bruising, which is likely multifactorial and due in part to capillary fragility and impaired platelet aggregation.³⁰ While prolonged bleeding times are uncommon, preoperative coagulation testing may be of benefit prior to undertaking major surgical procedures such as spinal deformity correction.

While increasing proportions of patients with OI are being treated with bisphosphonate medications, the optimal perioperative administration of these medications is unknown. Animal studies have suggested that bisphosphonate medications may delay the process of long bone fracture healing,^{31,32} however, there are scant clinical data in patients with OI to guide clinical decision making. Munns et al. undertook a retrospective logistic regression analysis of patients with OI who sustained a lower limb fracture or underwent a surgical osteotomy to determine whether pamidronate therapy had a differential effect on healing rates.³³ The authors found that improved mobility was the most significant factor associated with nonunion after 12 months in both groups. Osteotomy remained independently associated with nonunion after adjusting for mobility status, but fracture did not, suggesting that osteotomies had lesser healing potential than fractures, or were more preferentially affected by pamidronate therapy. Older patient age and osteotomy of the tibia were also found to be independently associated with nonunion. Given the concern for impaired bony healing, it is our preference to withhold bisphosphonate treatment prior to a planned spinal fusion; however, current data is insufficient to form a definitive recommendation on whether or not bisphosphonate medications should be held, and, if so, for what duration. The decision to continue bisphosphonate medications perioperatively must be made on an individual basis in collaboration with the patient's medical or endocrine physicians after weighing the reduction

Figs. 24.3A to F: Halo gravity traction for gradual thoracolumbar deformity correction followed by posterior spinal fusion in a patient with Sillence type III osteogenesis imperfecta.

in fracture risk and improved comfort with scheduled bisphosphonate treatment versus the potential for increased time to spinal fusion.

NATURAL HISTORY OF SPINAL MANIFESTATIONS

While OI affects the entire body, its effects on the axial skeleton are especially morbid and difficult to treat. Abnormalities have been reported at all levels of the spine, including deformity of the craniocervical junction, cervical kyphosis, thoracic kyphoscoliosis, lumbar hyperlordosis, spondylolisthesis, and sacropelvic dysmorphism. An understanding of the natural history of these conditions is essential prior to considering surgical intervention, which may present additional technical challenges specific to the disease process.

The calvarial bones are frequently thin and fragile in OI. Skull malformations may be avoided in some children with early medical treatment and careful change of position in infancy to avoid prolonged compression fractures on one segment of the skull, in the authors' experience. Thinning of the calvarial bones has implications for treatment of spinal disease, particularly with regard to the use of halo gravity traction. This necessitates the use of multiple pins (typically 8 or more), and the pins should only be finger-tightened. The pins must be monitored closely, as the authors have observed complications including skull fracture, pin penetration, or even skull elongation, during halo gravity traction in patients with OI.

Radiographic abnormalities of the craniocervical junction are commonly observed in OI. While these are most often asymptomatic, progressive deformity may result in compression of the cervical spinal cord and brainstem,

Figs. 24.4A and B: Posterior spinal fusion for progressive thoracolumbar kyphoscoliosis and spondylolisthesis in a patient with Sillence type IV osteogenesis imperfecta.

resulting in syringomyelia, hydrocephalus, seizure activity, or death.^{34,35} Neurologic manifestations are variable, and may also include headache, ataxia, apnea, quadriplegia, lower cranial nerve palsy, dysphagia, nystagmus or hyper-reflexia.³⁶ Sillence et al. initially described a prevalence of 25% for craniocervical abnormalities, with neurologic involvement from basilar impression most common in patients with OI type IVB.³⁷ A more recent cross-sectional study by Arponen et al. found a prevalence of 37% in their series of 76 patients with Sillence types I, III, and IV OI.³⁸ These were grouped into three types: platybasia (flattening of the anterior cranial base angle), basilar impression, and basilar invagination. Importantly, 44% of affected patients were noted to have multiple abnormalities. Kovero et al. reported rates of platybasia, basilar impression, and basilar invagination of 11.1%, 35.2%, and 22.2% respectively in their series of 54 patients with OI.³⁹ Cheung et al. identified the patient's height Z-score as the single most important independent predictor of craniocervical involvement in asymptomatic patients with OI.⁴⁰ No significant correlation was found with other putative factors, such as age, gender, blue sclerae, lumbar spine bone mineral density, or underlying genotype. In addition, no association was identified with prior bisphosphonate use, suggesting that bisphosphonates are not protective against progressive craniocervical junction deformity. While less commonly observed, myelopathy or tetraparesis has been described secondary to severe cervical kyphosis in OI.^{41,42}

Thoracic kyphoscoliosis is the most common spinal finding in OI, and it is a frequent indication for surgical

intervention (Figs. 24.4A and B). Manifestations are variable, but a predominance of thoracic kyphosis is characteristic.⁴³ Curve progression is often rapid, most likely due to ligamentous hyperlaxity and cumulative insufficiency fractures of the vertebrae and rib cage. These factors also conspire to limit the efficacy of bracing, which is largely unable to prevent truncal shortening and may ultimately worsen thoracic deformity and pulmonary function.^{11,29,44,45} The presence of numerous biconcave vertebral bodies has been reported in patients with more severe congenital variants of OI, and it is associated with the development of scoliotic curves $>50^\circ$ but not necessarily of thoracic kyphosis.^{46,47} However, Englebert et al. observed that scoliosis typically precedes the onset of pathologic kyphosis. The authors also noted that earlier achievement of antigravity and motor milestones was associated with delayed onset of spinal deformity.¹³ Watanabe et al. demonstrated a correlation between Z-scores of bone mineral density and body mass index with scoliotic curve Cobb angles in OI.⁴⁸ Indeed, thoracic curves with Cobb angles of $>60^\circ$ have been found to be strongly associated with decreased vital capacity and self-reported physical health component scores in OI.¹² These findings reinforce the role of systemic medical treatment for bone mineral density in order to prevent curve progression and potential respiratory compromise, though this has not yet been definitively demonstrated given the relatively limited cumulative experience with bisphosphonate treatment in these patients.

Maintenance of sagittal balance is essential for ambulation and sitting, and regional sagittal plane deformity

may result in compensatory curve progression. As such, it is difficult to separate the etiologies of such findings in OI as lumbar scoliosis or hyperlordosis, spondylolisthesis, and pelvic obliquity or dysmorphism. Abelin et al. performed a quantitative analysis of sagittal alignment in a cohort of patients with OI compared to healthy controls.⁴³ The authors observed a significant increase in upper thoracic kyphosis in the OI group without compensatory lumbar lordosis, resulting in anterior offset of the thorax. In the absence of increased lumbar lordosis, such changes mandate retroversion of the pelvis to maintain global sagittal balance. This may subsequently prevent ambulation in patients with concomitant hip flexion contractures.⁴⁹ There are multiple reports of a potential association between bony fragility and spondylolysis in OI,⁵⁰⁻⁵² though Verra et al. initially observed pars defects in only 5.3% of patients with OI; a rate similar to that of the general population.⁵³ More recently, Hatz et al. reported an 8.2% rate of spondylolysis occurring at an average age of 7.5 years in their review of 110 ambulatory patients with OI.⁵⁴ The authors also reported spondylolisthesis in 10.9% of patients occurring at an average age of 6.5 years. Spondylolisthesis in OI may be either isthmic or dysplastic in nature, as high-grade multilevel spondylolisthesis may be seen in association with severe pedicle elongation and lumbar hyperlordosis in the absence of pars defects.^{55,56}

SURGICAL INDICATIONS AND CLINICAL OUTCOMES

Fractures occurring with minimal trauma are a hallmark of OI. While not as common as those affecting the appendicular skeleton, fractures of the spine are an important source of morbidity in OI and may necessitate surgical intervention in rare cases. The vast majority of spinal fractures are compression fractures of the thoracolumbar vertebral bodies that may be relatively occult, and their accumulation may contribute to spinal deformity. In the absence of severe pain, deformity, or neurologic involvement, nonsurgical management is preferred in most cases. While these fractures may have an atypical radiographic appearance, the familiar anatomic approach to determining whether injury patterns are stable or unstable is useful in determining whether surgical intervention is warranted. Special consideration must be given to the impact of ligamentous laxity, if present, on the competence of the posterior ligamentous complex in the absence of obvious bony injury. Compression fractures may also be seen in the

cervical spine, as highlighted by Leng et al.⁵⁷ The authors reviewed two representative cases in neurologically intact patients, illustrating their decision for nonsurgical management of a stable injury versus circumferential fusion for an unstable injury with progressive deformity despite bracing. Similar principles apply to management of other cervical spinal injuries, as patients with OI typically have normal fracture healing potential despite baseline fragility. Indeed, there are multiple reports of successful nonsurgical management of traumatic spondylolisthesis of C2 with collar immobilization in patients with OI.⁵⁸⁻⁶⁰ A high index of suspicion for spinal injury must be maintained in any patient with OI who has abnormal neurologic findings, even without a history of trauma. Ziv et al. reported a case of paraplegia with sensory sparing from bilateral pedicle fractures and cervical spondyloptosis after a low-energy fall and subsequent chiropractic manipulation.⁶¹ The authors chose halo traction followed by anterior decompression via costotransversectomy and staged noninstrumented long posterior fusion with good postoperative recovery of neurologic function.

Given the similarity of compression fractures in OI to those commonly observed due to osteoporosis, many have sought to apply vertebroplasty and kyphoplasty techniques to this patient population in order to alleviate pain and prevent progressive deformity. Vertebroplasty in OI was first reported by Vasconcelos et al., who made a technical note of transient intraoperative hypotension without evidence of cement embolism, paralleling the experience of cement use in arthroplasty.⁶² Rami et al. first reported long-term clinical follow-up on one case of percutaneous vertebroplasty at T10 in a patient with OI, noting complete resolution of pain at 1 week postoperatively that endured throughout the 17-month follow-up period.⁶³ Tozzi et al. also reported a case of vertebroplasty in OI that was remarkable for intravenous cement embolization that necessitated a successful open pulmonary embolectomy.⁶⁴ While not unique to OI, concern exists regarding the higher potential for fractures adjacent to those treated by cement augmentation. Indeed, Kaso et al. noted adjacent-level fracture after a fall in a patient with OI who had just undergone vertebroplasty.⁶⁵ The authors treated this fracture as well with vertebroplasty and bracing and reported a good eventual clinical outcome at 11 months postoperatively. Long-standing OI frequently results in distorted bony anatomy, often making it difficult to discern pre-existing from acute deformity and increasing the complexity of typical surgical exposures and percutaneous

access routes. However, the severity of osteoporosis in OI may actually be exploited for the purposes of percutaneous access to the lower lumbar spine, as a transiliac trajectory to the L5 pedicle has been successfully reported for L5 vertebroplasty in a 66-year-old patient with OI.⁶⁶ Recent interest in kyphoplasty as a means to potentially reduce post-traumatic kyphosis has led to its application in OI as well. Hardenbrook et al. reported on the use of kyphoplasty in combination with silicate-substituted calcium phosphate in a young patient with OI and multiple-level compression fractures.⁶⁷ This treatment option theoretically allows for biologic restoration of more physiologic bone density in OI, thereby reducing the risk of adjacent-level fracture, though no long-term data are available to confirm its efficacy for this application. Successful use of cement as a bone void filler following kyphoplasty in OI has also been reported, with good relief of pain and no adjacent fractures over 9 months of follow-up.⁶⁸ While such case reports are encouraging, it is important to note that vertebroplasty and kyphoplasty in OI remain experimental techniques, as there is insufficient evidence to make a systematic assessment of their safety and efficacy in this patient population.

A feared and potentially lethal consequence of OI is progressive craniocervical deformity leading to compression of the spinal cord and brainstem at the foramen magnum. A variety of surgical approaches have been described to address this complex problem. Initial surgical efforts consisted of posterior suboccipital and cervical indirect decompression; however, posterior decompression alone was associated with recurrence of symptoms and the need for subsequent occipitocervical fusion.^{34,69,70} Harkey et al. reviewed their early experience treating eight cases of basilar impression with neurologic involvement, in which they advocated for primary anterior transoral decompression followed by staged posterior occipitocervical fusion.⁷¹ The authors reported the use of a LeFort I midface osteotomy to improve anterior exposure when necessary. Up to 2 weeks without skeletal traction elapsed between stages. Six of eight patients experienced long-term neurologic recovery with one death in the perioperative period from complications of bronchopneumonia and sepsis prompting eventual withdrawal of care. Sawin and Menezes subsequently reviewed their series of 25 patients with osteochondrodysplasias (18 with OI) undergoing surgical intervention for craniocervical abnormalities.³⁶ An algorithmic approach to treatment was proposed, with asymptomatic patients first undergoing bracing with a

Minerva-type orthosis. The development of symptomatic hydrocephalus prompted ventriculoperitoneal shunt placement. Deformity progression despite brace immobilization or development of symptomatic anterior neural compression prompted a trial of cervical traction. The authors distinguished between deformity that was reducible or irreducible with traction, performing posterior-only decompression and fusion for reducible cases, and staged anterior decompression with posterior fusion for irreducible cases. Patients undergoing fusion were placed in halo or orthotic immobilization for a mean duration of 8.2 months postoperatively until radiographic evidence of bony union was noted. Importantly, in the twelve patients undergoing halo immobilization, only one superficial pin-site infection was encountered, with no complications due to fragility of the calvarial bones. Good to excellent results were reported in 22 of 25 patients over the mean follow-up period of 5.9 years. Anterior approaches with transoral-transpalatopharyngeal exposures are technically formidable, requiring a multidisciplinary surgical team and sophisticated perioperative care. As a result, others have advocated for gradual preoperative reduction, with or without halo traction, followed by posterior decompression and occipitocervical fusion.⁷²⁻⁷⁵ While such results are encouraging for patients with reducible deformity, the poor quality of the bone formed in OI does not guarantee that successful posterior fusion alone is sufficient to prevent recurrent anterior compression or hydrocephalus. The long-term outcomes of combined anterior decompression and posterior stabilization were reassessed by Ibrahim et al., who examined cases occurring over a 21-year period with a median 10-year follow-up period.⁷⁶ The combined approach demonstrated optimal outcomes in patients with higher preoperative functional scores, as well as largely durable relief of neurologic symptoms over the follow-up period in patients who experienced immediate postoperative improvement. All patients underwent elective tracheostomy and gastrostomy placement to facilitate the anterior extended maxillectomy and recovery period. Despite these precautions, high rates of complications were observed, including respiratory infection, dysphagia, nasal speech, surgical wound infection, and depression. The extensive morbidity and prolonged hospital course associated with this highly invasive procedure has motivated the development of endoscopic techniques for anterior decompression. Applying techniques applied for decompression of cervicomedullary rheumatoid disease, Hansen et al. reported a case of endoscopic transnasal

resection of the clivus, anterior arch of the atlas, and odontoid tip in a patient with OI and symptomatic basilar invagination.⁷⁷ The patient was repositioned and a posterior occipitocervical fusion was subsequently performed. Endoscopic techniques have the potential to spare the patient considerable morbidity associated with an open transoral or transmaxillary approach, but these are technically challenging and require the use of intraoperative image-guided navigation. Menezes more recently reviewed his 20-year experience with treatment of craniocervical abnormalities in osteochondrodysplasias, including 28 patients with OI.⁷⁸ While the treatment approach evolved over time, he noted the later relative success of bracing with a custom Minerva-type occipitocervical orthosis, along with nighttime cervical collar traction as needed, in preventing craniocervical deformity progression as assessed by yearly magnetic resonance imaging (MRI). This may be most effective during early adolescence, when the rate of symptomatic deformity progression was noted to be highest. Hydrocephalus was assessed independently and treated by ventriculoperitoneal shunt placement when necessary. This treatment protocol was successful in preventing the need for anterior transoral decompression with posterior fusion in all but approximately 20% of patients with OI and related osteochondrodysplasias.

For the patient with symptomatic craniocervical compression, we recommend an initial trial period of halo gravity traction under strict neurologic surveillance, followed by repeat imaging with computed tomography and MRI. If a satisfactory reduction is achieved, an *in situ* instrumented posterior occipitocervical fusion may then be performed. Anterior approaches are considered only for cases refractory to indirect reduction techniques, as the morbidity and associated complications as noted previously are significant. These factors and expected outcomes must be carefully discussed with the patient and family prior to surgical planning. In addition to craniocervical junction abnormalities, deformity of the subaxial cervical spine is a rare but challenging manifestation of OI. Daivajna et al. described a case of myelopathy due to progressive cervical kyphosis that developed despite a prior posterior cervical fusion.⁴² Due to the distorted anatomy and head position, the authors report use of an anterolateral approach with a Y-shaped incision to gain exposure for corpectomies and cage reconstruction.

Thoracolumbar kyphoscoliosis is another spinal manifestation of OI that may have severe morbidity and remains challenging to treat despite advances in spinal instrumentation. Early literature on spinal deformity in OI was

primarily descriptive, with few early reports of Harrington instrumentation and posterior fusion for deformity correction.⁴¹ Cristofaro et al. were among the first to systematically report results from a series of 49 patients with OI.⁷⁹ Of these, 35 had some form of spinal deformity, and eight ultimately underwent surgical correction. A combination of preoperative traction, Harrington instrumentation, and noninstrumented techniques were used, with postoperative bracing in all cases. The authors emphasized that significant deformity correction was not achievable, and that the primary goal of surgery was stabilization *in situ*. Pre- and postoperative functional status was largely conserved, and no loss of correction or pseudarthrosis was seen over 9–12 months of follow-up. Benson et al. were also early advocates of operative intervention for spinal deformity in OI, reporting on an early series of 12 patients undergoing instrumented and noninstrumented posterior fusions.¹¹ The authors used cement augmentation of the hook sites, and observed a slight advantage in subsequent deformity correction with the use of instrumentation. Yong-Hing and MacEwen undertook a survey of the Scoliosis Research Society membership, gathering data on 121 patients with OI and spinal deformity treated by bracing, surgery, or both.²⁹ Sixty of these patients underwent surgical intervention; 55 had a posterior, four had an anterior, and one had a combined anterior/posterior fusion. The mean age at which surgical correction was performed was 15.6 years. The authors again noted more durable correction with instrumentation; however, they also detailed the numerous technical complications associated with its use. These included intra- or postoperative hook cutout, rod breakage, and sacral bar migration. One or more perioperative complications were present in 16 of 39 patients undergoing instrumented fusions, versus 2 of 16 without instrumentation. Hanscom et al. published a radiographic classification of OI based on data from a series of 64 patients.⁴⁵ The classification incorporated data from the appearance of the long bones, vertebral bodies, pelvis, and ribs, and it was applied to the 43 patients in the series with spinal deformities to assess prognostic value. Curve progression was not uniform in patients with type A disease (a mild variant with bowing of the long bones in relative isolation) but was near-universal in types B through E. Of these patients, 13 ultimately underwent surgical intervention. Instrumentation was used in 12 of 13 cases, beginning with Harrington compression-distraction rods but reflecting a trend toward increasing use of segmental Luque-Galveston techniques over time. Casting or bracing was used for 6–9 months postoperatively.

Of note, the authors observed gradual loss of correction over the follow-up period in several patients despite radiographic evidence of a solid fusion mass. They concur with prior authors' recommendations for considering early surgical intervention for curves between 40° and 50°, as more rapid progression has been observed after this threshold.⁸⁰ In addition, the amount of correction obtainable in OI is severely limited by poor bony fixation. To address this concern, the use of preoperative halo gravity traction has been employed in order to achieve gradual correction facilitating a subsequent *in situ* fusion. Gitelis et al. reported use of the technique, followed by staged anterior and posterior instrumentation with cement augmentation, for scoliosis correction in OI.⁸¹ Janus et al. subsequently described in detail a series of 20 consecutive patients with OI and scoliosis treated with preoperative halo gravity traction.⁸² The authors noted migration of the halo when six pins were used according to their standard protocol, prompting an increase in the number of halo pins to ten. With this fixation, traction of up to one-half body weight was possible for a mean period of 90 days. Once serial radiographs showed no further evidence of curve correction with traction, posterior *in situ* fusion was performed with Cotrel-Dubousset pediatric instrumentation in 18 patients, or Harrington instrumentation in 2 patients. Halo and orthosis use was continued postoperatively. The authors report obtaining additional iliac crest bone grafts from close relatives of the patients immediately prior to surgery when required. Mean pretreatment, immediate preoperative, and postoperative coronal plane Cobb angles were 78°, 53°, and 51°, respectively. The mean scoliosis correction achieved with traction was 25° (32%); this decreased to 19° (25%) over the follow-up period. Mean pretreatment, immediate preoperative, and final follow-up sagittal plane Cobb angles were 56°, 42.5°, and 44°, respectively. Mean kyphosis correction from pretreatment to final follow-up was 12° (21%). Improvements in ambulatory capacity were noted in 7 of 20 patients; no patients experienced a decrease in functional status following surgery. The authors acknowledge that the use of preoperative traction is controversial and concede that it is difficult to attribute their results to the use of traction, modern segmental instrumentation, or both. However, they conclude that preoperative halo gravity traction was generally well-tolerated, is particularly suited to correction of spinal deformity in OI due to the combination of ligamentous laxity and poor bone quality and propose that it may facilitate conditioning and rehabilitation in the

perioperative period. Tolboom et al. undertook a detailed assessment of functional outcomes and patient-perceived competence in a series of 11 patients with OI undergoing spinal fusion for scoliosis correction.⁸³ Long constructs from T2 to L5 were created in all except for one case in which thoracic fusion alone was performed. A posterior approach with Luque instrumentation was used in 7 cases and Cotrel-Dubousset instrumentation in 3 cases. An anterior approach was used in one patient. Mean preoperative and postoperative coronal plane Cobb angles were 55° and 39°, respectively, yielding a mean correction of 20° (36%). Additional outcome measures included a validated six-component self-competence scale obtained pre- and postoperatively in all patients. No significant changes were observed in functional capacity and ambulatory status at final follow-up. Trends toward significant improvements were seen in several of the other outcome measures, but only self-reported scholastic competence was found to demonstrate a statistically significant increase over the follow-up period. Four patients required additional surgery—one for deep infection and three for proximal junctional kyphosis. The authors conclude that surgical intervention for scoliosis in OI has no deleterious effects on function and may result in improvements perceived self-competence. They note that the patients in their series were not undergoing bisphosphonate treatment and postulate that this may help prevent curve progression in both the pre- and postoperative states.

It is important to consider the impact of spondylolisthesis, if present, when addressing sagittal plane deformity in OI. Hanscom et al. reported three patients with coexistent scoliosis and spondylolisthesis in their series, and the fusion construct was extended to the sacrum in one patient with a grade III spondylolisthesis.⁴⁵ Spondylolisthesis has also been reported inferior to the fusion construct following deformity correction in OI,⁸⁴ and the impact of increased bony fragility must be considered when selecting the end vertebrae of a long fusion. Basu et al. reported two cases of spondylolisthesis due to pars elongation in association with thoracic scoliosis in OI.⁵⁵ The authors treated one case of progressive spondylolisthesis and lumbar hyperlordosis with a retroperitoneal approach and noninstrumented anterior fusion from L3 to the sacrum using tricortical interbody bone grafts. The patient was placed in a plaster cast for 3 months, followed by orthosis immobilization for an additional 3 months. Successful fusion was noted, but progression of thoracic scoliosis prompted combined anterior/posterior fusion from T1

to L1 at 18 months following the lumbar fusion. Ivo et al. reported three cases of spondylolisthesis in OI, also due to pars elongation.⁵⁶ One patient underwent surgical intervention for severe elongation of pedicles L2 to L5 and a preoperative L3 to S1 sagittal Cobb angle of 136°. The authors chose a posterior approach with a laminectomy and posterolateral fusion using Cotrel-Dubousset instrumentation. The distorted anatomy of the pedicles resulted in partially extrapedicular screw placement. Slight postoperative improvement in lumbar pain was noted, with successful fusion and no further progression of the lumbar deformity. Of note, instrumentation prominence and pressure sore formation necessitated gradual removal of the instrumentation over 6 years following surgery. Ambulatory capacity was preserved until eventually limited by progressive pelvic deformity and acetabular protrusio.

TECHNICAL CONSIDERATIONS

Surgical intervention in OI presents a number of unique challenges to the surgeon. When considering the fundamental roles of decompression or stabilization in spinal intervention, several principles emerge that may guide the treatment approach. Realistic goals and careful preoperative planning with attention to these principles can help ensure positive outcomes and minimize the occurrence of complications. The approach must be careful and meticulous to minimize bleeding given the variable coagulopathy often encountered in OI. Exposure of the spine in a sequential fashion may aid in decreasing blood loss. We recommend the use of predominantly monopolar cautery, and the Cobb elevator must be used with caution so as not to fracture the posterior lamina.

The limitations of bone quality in OI cannot be overstated. In severe cases, the bone is of such abnormal consistency that it may be cut with a blade similar to other soft tissues. In general, acute intraoperative reduction or deformity correction is to be avoided whenever possible in favor of gradual preoperative correction. The ligamentous laxity frequently observed in OI helps facilitate this approach. Halo gravity traction is a useful technique for gradual correction of craniocervical or thoracolumbar deformities, but it requires maximizing the number of pin sites and close observation to prevent complications. Following traction, the goal of surgery subsequently becomes decompression, decortication, and placement of bone graft and/or substitutes to facilitate fusion with minimal or no correction obtained intraoperatively. Distorted

anatomy or concerns about pelvic fracture propagation often limit the amount of available bone graft for long fusion constructs, though the spinal pathology may be so severe as to warrant the extensive use of autograft for its superior healing potential despite these risks. If required, banked allograft bone or other bone substitutes may be used to augment the available allograft. Obtaining biologic fixation and expediting bony fusion is especially important in OI, as instrumentation is prone to early pullout or failure. Circumferential fusion with bone graft is preferable where possible, as this provides additional protection against curve progression that may occur even with a healed posterolateral fusion.

The improved fixation obtainable with the use of modern segmental instrumentation has allowed for additional correction, earlier mobilization, and lesser reliance on external casting or bracing postoperatively. Despite these benefits, there are many circumstances where the extensive use of pedicle screws is not feasible or may be detrimental. Distorted pedicle anatomy, as in dysplastic spondylolisthesis, may not provide a sufficient bony conduit for screw placement. Typical techniques for screw placement using the pedicle probe or awl are inadvisable and must be replaced by drilling techniques (either with the hand drill or powered oscillating drill; in some cases a 2.5-mm drill must be used). To achieve safe drilling, at least on the concavity and apex of the curve, we recommend direct exposure of the medial wall of the pedicle through a small laminotomy. While trying to insert a pedicle screw, one must always remember that this may result in the fracture of the pedicle and a loss of fixation. Adult patients with severe OI and scoliosis are frequently of small stature, and may necessitate the use of pediatric instrumentation (5.0- or 5.5-mm rods, 4.0-mm screws). Dilation of small or sclerotic pedicles to accommodate even pediatric pedicle screws may not be possible without resulting in a fracture. At such levels, sublaminar wires or tapes may be used, as it is preferable to achieve some form of fixation at every possible level rather than forgoing fixation at levels not amenable to screw placement. Sublaminar wires or hooks may even be used to supplement intact pedicle screws as needed. To augment screw fixation, polymethylmethacrylate bone cement may be used in two different ways: either by injection of the cement into the screw hole followed by pedicle screw insertion, or by embedding the heads of the implants in cement. The latter technique is especially useful at the proximal and distal aspects of the construct.

CONCLUSION

Osteogenesis imperfecta is a disorder of collagen synthesis with wide-ranging skeletal manifestations. Because of the incredibly diverse nature of the OI population and the variable severity of the disorder, each patient must be evaluated as thoroughly as possible for bone structure, bone quality and density, and associated soft tissue abnormalities. Spinal pathology occurring in OI may be significantly morbid and especially difficult to treat. A number of surgical strategies have been described to address abnormalities of the craniocervical junction, insufficiency fractures, and thoracolumbar spinal deformity. Surgical intervention in OI remains technically challenging, though new methods and instrumentation continue to result in improved outcomes. Awareness of established techniques and treatment principles in OI may help guide surgical decision making and prevent complications. At present, the effect of medical management with bisphosphonates on the incidence and progression of spinal deformity has not been adequately studied. Early experience suggests that bisphosphonate therapy may result in better surgical fixation and possible improved correction of deformity, though it remains unclear if this will improve long-term maintenance of correction or result in increased rates of pseudarthrosis.

LEARNING OBJECTIVES

- Recognize the spinal manifestations of osteogenesis imperfecta (OI)
- Identify the impact of associated spinal deformity on overall health and quality of life in patients with OI
- Understand specific technical considerations related to spinal surgery in patients with OI.

- » Treatment

INTRODUCTION

Scheuermann's disease is named after the radiologist Holger Scheuermann, who first described the characteristic lesions of watchmakers' apprentices in 1920.¹ His initial hypothesis was that the disease was caused by aseptic necrosis of the ring apophysis of the vertebra (the cartilaginous plate surrounding the vertebral nuclei which give rise to secondary ossification). However, this theory was reassessed following the works of EM Bick and JW Copel² who demonstrated that the apophysis plays no role in growth and necrosis has never been observed. The most recent histological studies have shown that the collagen content of the vertebral endplates is relatively low³ and explains the growth disorder. It is therefore a primary and not a secondary ossification disease.

Scheuermann's disease or juvenile kyphosis or juvenile osteochondrosis of the spine are one and the same disease resulting in pathological kyphosis in adolescents caused by damage to the vertebral bodies. The exact pathophysiological cause of the disease has not been clearly established, but autosomal dominant familial forms indicate genetic involvement. Factors associated with the disease include male gender, obesity and tallness, but their exact role is unknown. Microtrauma and sporting activities are more debatable factors.

CLINICAL ASPECTS

Scheuermann's disease is a relatively common disease observed in both its clinical and radiological form and its

Fig. 25.1: Clinical presentation of “upper” Scheuermann's disease.

asymptomatic form (50–60% of adolescents are affected when vertebral plate irregularity is used as a radiological definition) (Figs. 25.1 and 25.2).

Typically, it is observed in boys of 15–16 years of age (earlier in girls) who consult either for spinal pain or for accentuated thoracic kyphosis. However, the disease may also be diagnosed following routine examinations. The pain is generally moderate but may be absent; it is mechanical in nature and most often transient. Kyphosis is the alarm sign for parents, general practitioners and school physicians. It appears progressively and is not particularly incapacitating for the patient.

Fig. 25.2: Clinical presentation of “lower” Scheuermann's disease.

A physical examination in the standing position (see Fig. 25.1) and then lying down permits an assessment of the degree of kyphosis and its correctability. The plumb line test is used to evaluate the distance between the apex of the kyphosis, the spinous process of C7, the spinous process of L3 and the upper part of the intergluteal cleft (equivalent to S2). This test is useful for patient follow-up. The examiner must assess the mobility of the vertebral column and examine the patient for gibbosity, which is usually minimal, but may indicate a slight rotation of the vertebral column. Examination in the dorsal and ventral recumbent positions is used to assess the correctability of the curvature.

The clinical signs of Knutsson⁴ and Edgren and Vainio⁵ are practically pathognomonic because they point to disharmonic growth.

Finally, the clinical examination should include gathering information for differential diagnosis. An in-depth neurological examination should be performed, but the results thereof are usually normal. The presence of any neurological sign rules out Scheuermann's disease, though anterior compression of the spinal cord has been encountered in rare cases. It should be noted, however, that vibratory pallesthesia and abnormal proprioception associated with slight motor dysfunction but no tendon reflex abnormalities are observed in 15% of cases.⁶ Secondary sexual characteristics should be noted in order to assess the child's development. The purpose of the examination is to eliminate secondary kyphosis and to assess the localization and degree of kyphosis, essential for long-term development and choice of a treatment strategy (Fig. 25.2).

The Murray study,⁶ a prospective study that included 67 patients with a mean kyphosis angle of 71°, contributed

Figs. 25.3A and B: (A) Typical appearance of vertebral bodies in Scheuermann's disease layered, irregular appearance of the vertebral endplates and wedging; (B) important kyphosis of 97°.

to a better understanding of the long-term development of the disease. The study involved clinical, radiological and respiratory assessments over a mean period of 32 years. The results were compared with those of a control group of 32 patients. The study patients suffered more lumbar pain, were more likely to have sedentary jobs and less spine extension mobility. They did not seem any way impaired in their daily activities or bothered by cosmetic appearance. Furthermore, no respiratory function disorders were found in patients presenting with a kyphosis angle of <90°. Those with a kyphosis angle >90° had restrictive lung disease. However, since only a few low-power epidemiological studies have been performed, no hasty conclusions should be drawn regarding disease-related complications, or on the awkwardness patients may feel about their appearance over the long term; but they should be taken into account when deciding on a treatment strategy from the range of available options.

IMAGING

The paraclinical assessment should comprise front and profile images of the patient in the standing position. Images should include the occiput and femoral heads to allow for analysis of spinal and pelvic sagittal balance parameters. The low radiation imaging system EOS (EOS Imaging Paris, France) provides the most reproducible measures. Assessment of bone age using the Greulich and Pyle method based on a single X-ray of the left hand or elbow is useful for evaluating spine maturation, as is Risser's sign.⁷

Typical radiological findings (Figs. 25.3A and B) include irregular vertebral endplates, which appear to be layered

(a flaky pastry aspect) with blunted anterior edges, disc space narrowing and multiple herniations of the nucleus pulposus associated with wedging of the vertebral bodies. Several radiological definitions exist for Scheuermann's disease and the first of these was established by Sorensen in 1964.⁸ His definition of the radiological criterion for diagnosis of Scheuermann's disease was wedging of 5° or more in at least three consecutive vertebrae. As for Bradford,⁹ the criteria include irregular vertebral endplates, loss of intervertebral disc space, wedging of at least one vertebral body and hyperkyphosis of >40°. However, there are several forms of the disease that do not comply with these definitions and whose signs are on the threshold between normal and pathological. There is no clear consensus among authors on the definition of pathological kyphosis: values range between 12° and 57° for Stagnara,¹⁰ between 20° and 40° for Roat, while for Bradford,⁹ it must not exceed 40°.

TREATMENT

Scheuermann's disease may be treated in a number of ways. Treatment should always be initiated with conservative methods that should be instituted as early as possible.

Conservative treatment is based on three approaches: hygiene and diet, physiotherapy and bracing.

Hygiene-dietary rules should be applied from the youngest age, with the prohibition of all passive vertical positioning of children with immature and defective vertebral columns. The child's standing and sitting positions must then be regulated, as should all its physical activities. The patient's position may be regulated by use of adapted school and home furniture, and by suitable physical exercise, i.e. stretching exercises that reinforce the muscles of the posterior vertebral column, and by avoiding postures that increase the kyphosis. Sports must remain recreational and all notion of competition should be forbidden.

Physiotherapy is essential for the management of Scheuermann's disease. For optimal results, the vertebral column must still be partially flexible and correctable. The efficacy of treatment is very dependent on the motivation of the patient and of the physiotherapist. The aim of treatment of postural abnormalities with spinal and pelvic imbalance is chiefly to reinforce the tone of the erector muscles of the spine, to stretch the contracted muscles and the curvatures. Furthermore, physiotherapy helps the patient understand the orthopedic treatment protocol, which is often difficult to endure.

An important aspect of conservative treatment involves the use of orthotic devices to stop disease progression,

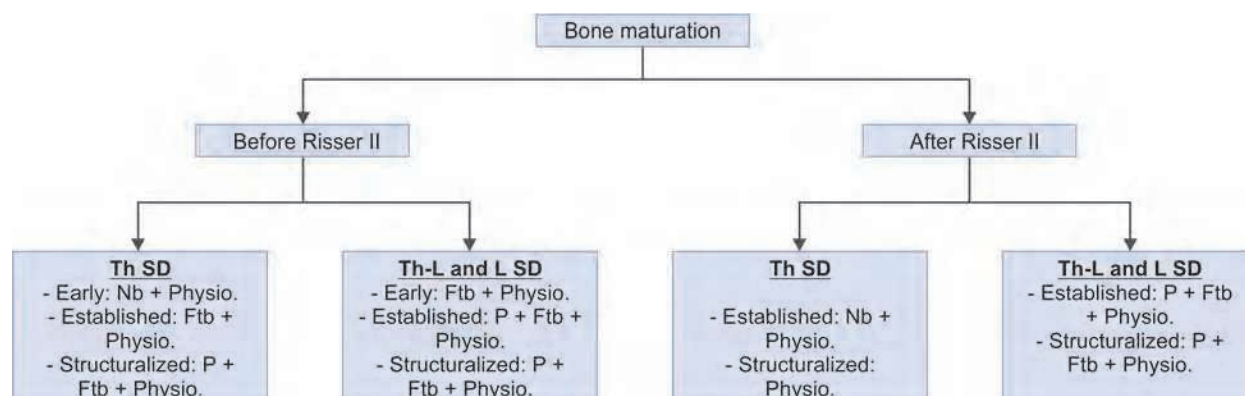

Fig. 25.4: Milwaukee-type brace.

reconstruct, rebalance and correct sagittal abnormalities. This very restrictive treatment often leads to major patient resistance, which makes it essential that patients and their families adhere to the treatment project. Young patients with early disease may be treated with a Milwaukee-type brace providing median posterior support (Fig. 25.4).

Many active-passive and passive braces have been described for the more severe forms of the disease. They generally comprise a posterior pad and two anterior pads. It is often necessary to start treatment by using the elongation-derotation-flexion casting technique to improve flexion of the vertebral column. The duration and modalities of treatment with braces have not been clearly codified. This conservative treatment is generally disappointing in the long term. Its main purpose is to stop the disease progression and prevent the development of a more severe form of the disease and to avoid surgery. Conservative treatment is rarely curative and is most effective when applied to young subjects. Garreau de Loubresse has established a decision tree for orthopedic management based on bone maturation (whether Risser's sign II has been reached or not), localization of the lesions (thoracic, thoracolumbar or lumbar) and on the stage of disease progression (early, established, structuralized) (Flowchart 25.1).¹¹

Surgery is an option for severe forms of the disease.

The methods used for surgical correction have been perfectly defined. They are all based on spinal fusion (arthrodesis) with anterior, posterior or circumflex autogenous grafting, associated with posterior segmental compression instrumentation to straighten the spine. There is still no consensus as to whether posterior or combined anteroposterior procedures are better.

Flowchart 25.1: Decision tree. Treatment strategy for Scheuermann's disease (SD).

(Physio: Physiotherapy; Nb: Night-time brace; Ftb: Fulltime brace; P: Plaster; Th SD: Thoracic SD; Th-L SD: Thoracolumbar SD; L SD: Lumbar SD).

**Fig. 25.5:** Ponte osteotomy.

The length of the spinal segment fused is also an important parameter. Long fusion (10–12 vertebrae on average) enables a better load distribution. The major risk associated with short fusion is postoperative angle loss and the appearance of over- or underlying junctional kyphosis, as in the series of Pejin et al.¹² Many authors consider that it is reasonable not to correct the initial curve by >50%, or the patient may suffer major neurological complications.

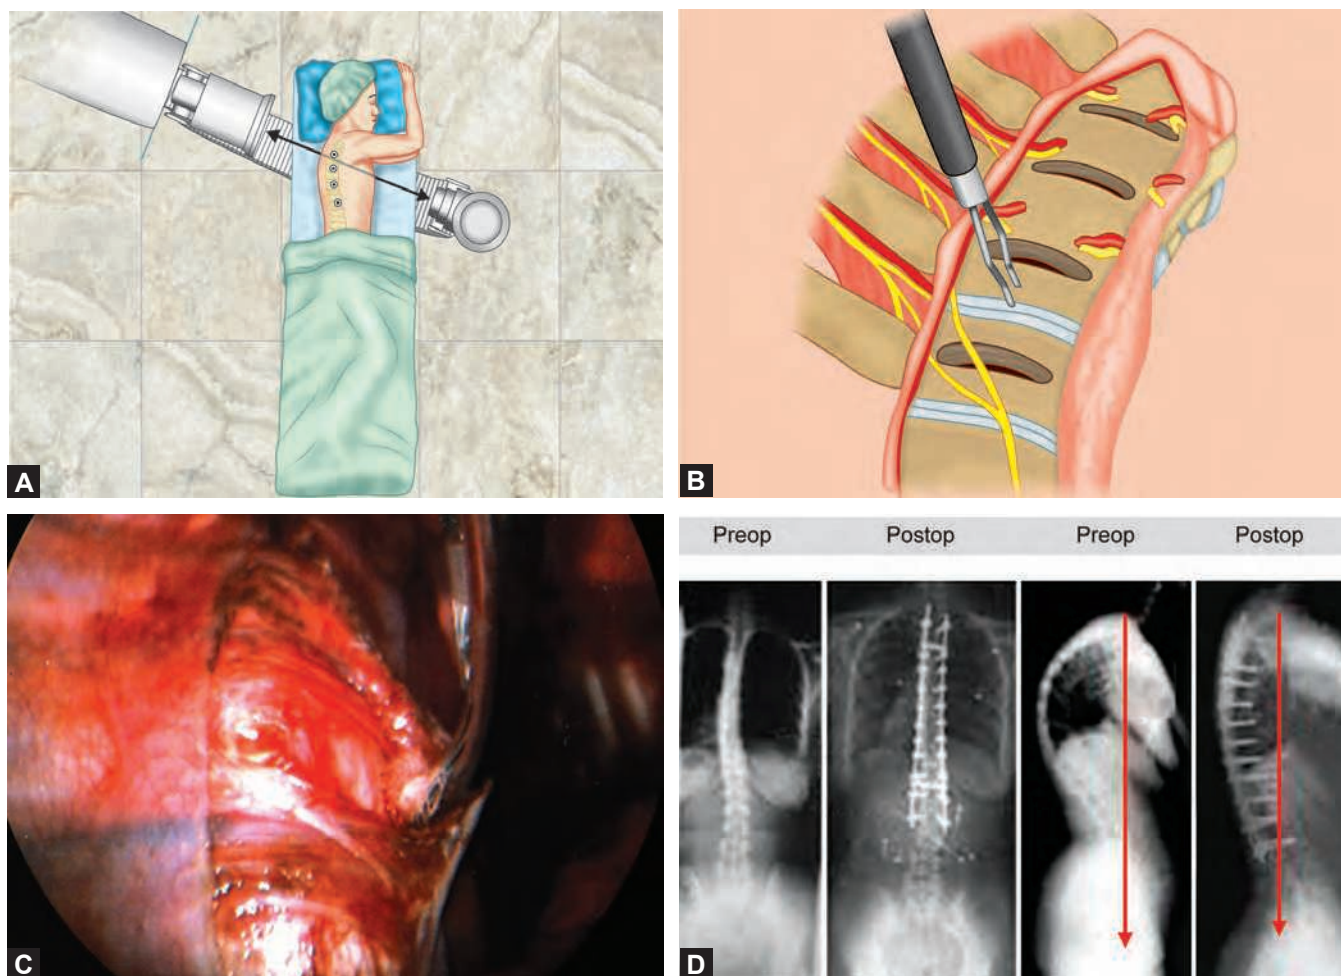

We recommend the Ponte posterior-only procedure (Fig. 25.5). It consists in bilateral resection of the posterior facets, also removing the isthmus, which produces

effective posterior compression provided that the disc maintains a certain amount of anterior flexibility. If the anterior disc opening is too wide, additional intersomatic grafting is recommended. In such cases, the procedure should be carried out by thoracoscopy. Where the anterior discs are very stiff, they must first be released by thoracoscopy (Figs. 25.6A to D) or by thoracotomy before the posterior procedure is performed, with or without Ponte osteotomy, but always with pedicle screw instrumentation and postoperative bracing.

Surgery for the treatment of Scheuermann's disease must only be used exceptionally in adolescents. Not only the significance of the deformity but also the complications associated with surgery⁹ and the good tolerability of balanced kyphosis must be taken into account. The use of intraoperative evoked potentials is essential to secure this corrective procedure, which may put the anterior spinal artery under pressure.

CONCLUSION

Scheuermann's disease is a juvenile kyphosis secondary to vertebral disc pressure and overload. Its impact is variable in adults and depends on where the lesions are located and whether or not the kyphosis is balanced. The shortcomings of treatment protocols, which only treat the sequelae, must be taken into account in the overall long-term management of patients. Screening and preventive management are of primordial importance in this disease.

INTRODUCTION

Familial dysautonomia (FD), first described in 1949 and termed Riley-Day syndrome,¹ is a rare genetic disorder with extensive autonomic and small-fiber sensory dysfunction. The condition is most aptly classified in the larger scheme of rare neurodevelopmental disorders labeled *hereditary sensory and autonomic neuropathies* (HSANs). It is defined as HSAN type III and distinguished from other HSANs by unique pathogenetics and predominant central and peripheral autonomic involvement. There are five reported HSANs of which FD is the most common, best studied, and remains of particular orthopedic interest due to prevalence of skeletal deformity in this population. The disorder's nonorthopedic concerns also present a unique challenge in the surgical and nonsurgical management of these patients.

EPIDEMIOLOGY AND GENETICS

There have been nearly 600 registered patients worldwide since 1970,² and are almost exclusively of Ashkenazi, or Eastern European, Jewish descent.^{3,4} Familial dysautonomia is transmitted in an autosomal recessive mode of inheritance with an estimated prevalence of one in 3,600 live births and a carrier rate of 1:27 to 1:36 among the Ashkenazim.^{3,5,6} One study identified a significantly higher carrier rate (1:18) among Ashkenazim of full Polish

background compared to non-Polish counterparts (1:99) suggesting the need for focused population screening.⁴ Males and females are affected equally. Notably, other HSANs do not share this well-defined ethnic bias.

The genetic defect has been mapped to the distal long arm of chromosome 9 (9q31-q33).^{3,7} A single noncoding, base-change mutation in gene *IKBKAP* (IkB kinase-associated protein) has been shown to be responsible for >99.5% of all reported FD cases.⁶ The mutation causes decreased splicing efficiency and a variable *IKBKAP* message. This produces an abnormally truncated IKAP protein product of the human elongation complex.^{3,7-9} Though initially believed to play a critical role in transcription, IKAP is now known to have a wide array of roles including histone acetylation, tRNA modification, and regulation of cell-surface transport.¹⁰ Two other very rare pathological FD gene mutations have been identified in heterozygous carriers. Both mutations are believed to disrupt phosphorylation.³

Despite the presence of homozygous *IKBKAP* mutation in this recessive disease, cells from patients with FD are capable of expressing wild-type *IKBKAP* message and associated elongator protein complex. The predominant mutation pattern in FD, hence, results in variable expression of the gene in a tissue-specific manner. Brain and nervous tissue from individuals with FD expresses primarily mutant *IKBKAP* mRNA, while fibroblast and

lymphoblast cell lines express predominantly the wild-type *IKBKAP* message. The molecular basis of this finding is yet unknown, but the discrepancy does suggest that neuronal cells are particularly intolerant of compensating for the missplicing.^{3,8,11}

■ NEUROPATHOLOGY

Familial dysautonomia is a progressive neurological disease with characteristic neuropathological findings that provide the structural basis for the biological and clinical manifestations of the disease. Though central, peripheral, and autonomic neurons are affected, much of our understanding is based on peripheral findings from nerve biopsies. Sural nerve biopsies have been classically used for tissue diagnosis. These findings illustrate incomplete neuronal development and limited survival of autonomic and sensory neurons leading to progressive neuronal degeneration.^{3,12,13} Sympathetic development is affected more significantly than parasympathetic.^{3,14} The greatest impact is seen on small, unmyelinated nerve fibers that mediate autonomic function and carry pain, temperature, and taste sensation. Larger myelinated afferent nerve fibers may also be deficient, including those that relay impulses from muscle spindles and Golgi tendon organs. This results in a decreased number of unmyelinated and small myelinated fibers leading to the broad clinical manifestation of autonomic dysfunction. Significant variability may exist in the presentation of this disease from patient to patient and over time. In fact, neuronal depletion in the dorsal root ganglia and spinal cord correlates well with the clinical progression of disease with age.³

Central nervous system dysfunction remains clinically apparent in individuals with FD, but thus far poorly defined without consistent qualitative anomalies found. However, more recent genetic studies do show altered expression of normal gene product in the central regions consistent with clinical evidence of central autonomic dysfunction.¹⁴

■ CLINICAL PRESENTATION AND DIAGNOSIS

The resultant multisystem dysfunction of FD is present at birth. Despite significant variability in expression, the diagnosis of FD is suspected clinically based on appreciation of five fairly consistent “cardinal” criteria: absence of overflow tears with emotional crying (alacrima), depressed patellar deep tendon reflex, decreased taste and absence

of lingual fungiform papillae, lack of axon flare with intra-dermal histamine, and documented Ashkenazi Jewish extraction.³ However, diagnosis can be definitively established by molecular genetic testing of *IKBKAP* in questionable cases.

In infancy, poor suckling and esophageal dysmotility can lead to stubborn feeding difficulties, aspiration pneumonia and eventually chronic lung disease. Relative insensitivity to hypoxia and vomiting crises can compound these issues. Due to vasomotor lability, infants often show signs of hyperhydrosis, temperature dysregulation, and blotchy erythema which in turn can be a source of significant physical and emotional stress. “Autonomic crises” are triggered due to stress, which manifest in 40% of individuals with FD sometime after 3 years of age. Crises refer to attacks of cyclical vomiting lasting 24–72 hours that are associated with hypertension, profuse sweating, apprehension and irritability. Breath-holding spells, leading to syncope, are also rather characteristic of FD in the first 5 years of life. Though no associated mortality has been reported, breath-holding spells do present significant risk for trauma and fractures.

Later in childhood, sensory ailments become more pronounced and orthopedic concerns become more apparent. Relative indifference to pain leads to corneal ulcerations, tongue maceration, self-injury, and accidental trauma leading to multiple, often unrecognized, fractures and avascular necrosis. In general, young patients with FD are hypotonic that may be due to a combination of central deficits and decreased tone from stretch receptors.⁹ Walking is expectedly delayed and appears ataxic due to poor sensory feedback from muscle spindle cells as well as vestibular nerve dysfunction. Speech is likewise mildly delayed and often characterized as nasal and slurred due to dysarthria.

Severe orthostatic hypotension without compensatory tachycardia is characteristic and due to decreased sympathetic vascular innervations. This does significantly limit the mobility and function of the adult patient. Episodic supine hypertension is a centrally driven finding that is less well understood. Inappropriate release of central catecholamines and exaggerated peripheral response due to denervation hypersensitivity is believed to be the etiology. Further manifestation includes bradycardia and cardiac arrhythmia often requiring pacemaker placement. Body temperature dysregulation is also a rather common presenting as hypothermia or severe fever. This, along with breath-holding-related hypoxia, has been linked to a major motor seizure disorder in FD.

Emotional lability is a prominent feature of FD. These episodes can lead to or intensify during autonomic crises. Treatment with benzodiazepines has been well documented. Most individuals are of low, normal intelligence but able to participate in their medical care.

■ ORTHOPEDIC MANIFESTATIONS

Orthopedic problems are common in FD and cause significant disability.^{15,16} Consistent musculoskeletal manifestations of FD include delayed walking, delayed puberty and short stature, ataxia, foot deformities, tibial torsion, osteochondritis, avascular necrosis, neuropathic joint deformity, osteopenia or osteoporosis due to gastrointestinal dysfunction, joint contracture, increased incidence of fractures, and most commonly spinal deformity.^{9,15,17,18}

Decreased pain perception, unsteady gait and lack of reflexive protective movements significantly increase the risk of inadvertent trauma. In a review of 182 FD patients, Laplaza et al. found that 60% of patients had one or more fractures at a rate of 1.4 fractures per patient, which was significantly higher than their healthy counterparts. Most commonly involved bones were the radius, tibia, and femur with a peculiarly high rate of proximal femur fractures in this population. Neuropathic joints manifested in 11% though believed to be an underestimation.⁹ The knee was the most frequently involved joint followed by the foot-ankle and hip.

Spinal Deformity

Spinal deformity is the most prevalent musculoskeletal problem in FD with a reported incidence ranging from 50% to 95% in surviving dysautonomia patients.^{16,17,19-21} Since no bony cause has been identified as the root of deformity progression, it is possible that focal demyelination in the ascending posterior columns of the spinal cord, thoracic nerve roots, and spinocerebellar tracts results in proprioceptive and kinesthetic changes.¹⁶

Scoliosis is the most common deformity pattern; however, there is a significant predilection for kyphosis in the FD population.¹⁹⁻²² The apex of kyphotic deformity is usually quite cephalad with 90% proximal to the fifth thoracic vertebra.²¹ Scoliosis is defined as $>10^\circ$ of coronal plane curvature and thoracic kyphosis is defined as sagittal plane curvature $>40^\circ$. Larger studies did not find a significant difference in prevalence between males and females.^{15,19}

Spinal deformity presents early in life and many cases are diagnosed prior to 2 years of age.¹⁷ Hayek et al. found that scoliosis and kyphosis were diagnosed on average at 8 and 9 years of age, respectively. At presentation, curve magnitudes of 60% of patients were rated as severe and only 18% rated as mild. And, unlike idiopathic scoliosis in which a majority of curves are the apex right thoracic and the apex left lumbar, 40% of FD patients present with left-sided thoracic curves.¹⁹ No means of predicting curve progression has yet been established, but curves progress during the adolescent growth spurt. Growth velocity is accelerated by growth hormone therapy used for management of short stature.²³

Reported curve characteristics vary widely with scoliosis seen in 25–56%, kyphoscoliosis seen in 25–73%, and pure kyphotic deformity seen in 2–4%.^{15,19,20} The curve pattern of scoliosis is also highly variable. Bar-On et al. found that the majority of patients have a single thoracic or thoracolumbar curve, while 35% had a double curve. Thoracic hyperkyphosis is more common in patients with a double major curve.¹⁵

■ MANAGEMENT OF SPINAL DEFORMITY

Conservative Management

Nonoperative treatment of spinal deformity has proven to be challenging, poorly tolerated and fraught with frequent complications. Despite this, most patients are initially treated in a custom orthosis. Bracing is often initiated around 10 years of age and continued for 3–4 years.¹⁵

Patients with FD have significant emotional lability that makes enforcing brace wear particularly difficult for the patients' families. The physical and emotional stress associated with this process can in fact be the trigger to autonomic crises. Approximately 40% of patients have a history of autonomic crises as discussed above. Additionally, relative thermal instability may also be troublesome with bracing and body casting leading to hyperthermia that has been linked to seizures in patients with FD.¹⁶ Patients should be monitored for euthermia and air conditioning used for elevated body temperatures.

Other than wear tolerance and poor compliance, brace-associated pressure ulceration is also common in the setting of decreased sensation and relative pain indifference. Frequent skin checks and regular brace fitting are important preventative measures. As kyphosis is a common component of spinal deformity in FD, the Milwaukee

brace had been classically prescribed; however, bivalve thermoplastic thoracolumbosacral orthoses are now more often used and somewhat better tolerated by patients.^{16,17,20} Bracing is also associated with decreased ability to exercise and a progressive increase in muscle weakness attributable to their disease, activity avoidance, and frequent respiratory infections.¹⁶ Others have noted increased rate of gastroesophageal reflux and aspiration pneumonias due to recumbent positioning and nightly gastrostomy feeds leading to their recommendation to discontinue overnight bracing.¹⁹

Albanese et al., in an early report on treatment results, reported brace intolerance in all of their patients.¹⁷ Hayek et al. found that despite bracing, 89% of curves progressed with thoracic and lumbar curve progression of 5° and 4° per year, respectively. Interestingly, they found association between curve magnitude and the change that occurred during bracing.¹⁹ Kaplan et al. found similar coronal plane curve progression but reported kyphosis to deteriorate at a rate of 9° per year.²⁰

Physical therapy has been shown to be effective as adjunctive management in milder curves.²⁴ Exercises and modalities should be individualized to address the patient's specific issues given the variability of disease presentation. Exercise, compression stockings, and increased fluid and salt intake help prevent symptomatic orthostatic hypotension. Focused occupational therapy to enhance oropharyngeal coordination may allow better feeding and help the patient's nutritional status and decrease aspiration risk drastically. Breathing exercises and regular respiratory therapy should begin at an early age to prevent recurrent pulmonary pneumonia. Musculoskeletal focus of physical therapy revolves around increased flexibility of the spine, core strengthening, gait training and postural exercises. To address kyphotic deformity, further exercises focus on strengthening the erector spinae, hyperextension exercises, and pectoralis stretching.²⁴ Electrical muscle stimulation has been used as adjunctive therapy, but lacks clinical support.

Surgical Management

The need for early treatment of spinal deformity in progressive neurological disorders was first recognized by Hensinger and MacEwen, who reported on the surgical management of a limited cohort.²⁵ However, multisystem involvement, a host of serious medical problems, and the risk of perioperative mortality in individuals with FD make surgical optimization, planning, and deformity correction

challenging. Still, surgical management is advantageous compared to observation or conservative measures if attempted at an early stage in the evolution of progressive spinal deformity.

In general, surgical management of scoliosis and kyphosis is indicated for curve magnitudes >40° and >65°, respectively, in patients who failed conservative management.¹⁵ However, attempts are made to delay arthrodesis until adolescence, as patients with FD are characteristically of short stature. Usually, a relatively short fusion is indicated and can serve to prevent further loss of stature due to progressive deformity. For severe deformity with cardiopulmonary compromise on initial presentation, it is not unreasonable to work toward operative management as the index procedure. The decision is further influenced by the patient's overall health and the readiness of their family.

Preoperative workup consists of liver, lung, and renal function testing, as well as electrolyte and nutritional assessment. Surgery should be done in a period free on frequent pulmonary infection and when the patient's family is free of other distractions or burden. In essence, a multidisciplinary team familiar with dysautonomia should work to optimize the patient.

On the day of the operation, it is important to maintain adequate hydration and avoid patient overstimulation and anxiety; anxiolytics are often required. Because of poor oral intake, chronic dehydration and prerenal azotemia are common in this population. These patients are admitted the day before surgery, since intravenous fluid resuscitation for 12 hours prior to anesthesia is recommended.²⁶ Because of increased aspiration risk, cimetidine has been used prior to anesthesia to reduce gastric secretions. Given the patient's relative insensitivity to hypoxia and hypercapnia, premedication with narcotics is avoided.

Intraoperative concerns include an autonomic crisis and cardiovascular collapse. Experienced anesthesia teams can avoid this with proper preparation, hydration, maintenance of intravascular volume, and blood replacement. Posterior spinal arthrodesis is preferred over anterior approach surgery to avoid postoperative pulmonary complications secondary to the transpleural surgical approach. Hybrid or third generation (all pedicle screw) instrumentation can be used, but osteopenia may challenge the strength of the bone-implant interface and the senior author has also employed sublaminar wires or cables to augment correction forces along with pedicle screws. Postoperatively, consideration can be given to

bracing patients to protect the spinal implants, but this is poorly tolerated for reasons described above.

Rubery et al. and Bar-On et al. reported on their series of surgical curve corrections. Scoliosis was reduced by 36–40% compared to the preoperative curve, but at longer follow-up only 18–20% reduction was maintained. The authors noted failure proximal and distal to the fusion. Kyphotic deformity was reduced by 12–20%, but at longer follow-up only 3–4% correction was maintained. Both studies found that the loss of correction in kyphosis occurred only proximal to the instrumented arthrodesis. Rubery et al. hypothesized that due to existing rigid cervical lordosis, patients develop sagittal imbalance following posterior thoracic fusion leading to proximal junctional failure and implant pullout. They addressed this by extending the fusion far cephalad in the thoracic segment and adding a cervical extension to the postoperative orthosis. Henderson et al. provided radiographic evidence to support this hypothesis by showing a 50% reduction of intervertebral flexion–extension excursions at all cervical levels other than C1–C2 in the FD population compared to normal values. C1–C2 excursion was 20% below normal values.²²

Kaplan et al. reported that all of their patients treated surgically, and the preoperative ataxia improved considerably and rapidly. These patients also had decreased rate of hospitalizations for pulmonary infections following surgery.²⁰

POSTOPERATIVE CONCERNS

Surgical management of spinal deformity in FD is met with frequent postoperative complications. Most common of these involved the skin, respiratory, and gastrointestinal systems.²¹ The most common single complication is pneumonia that can lead to generalized sepsis or extended intensive care stays. Failed fixation in the form of screw pullout, implant breakage, and hook disengagement has been reported by multiple authors. Bar-On et al. found curve progression at the site of arthrodesis in association only with instrumentation failure. Pseudoarthrosis is rare in this population, and despite all-posterior fusion in a relatively young population, no crankshaft phenomenon is reported.²⁰ Cyclical crisis patterns may arise with sufficient stress in any affected individual with FD in the perioperative period. Stress can be emotional due to anxiety or physiological due to infection, postoperative pain, visceral pain from constipation, sleep deprivation, or fatigue.

Despite a myriad of postoperative concerns and complications, reported surgical mortality is low in several larger studies.^{15,20,21}

PROGNOSIS

Patient survival and quality of life have significantly improved in the past 50 years.¹⁰ With greater research across multiple disciplines and an established patient registry, we now know far more about the disorder and the care of individuals with FD. Prior to 1960, only 50% survival past 5 years of age was predicted, though today 50% of FD patients live beyond 40 years of age.³ This drastic improvement in life expectancy is in part due to early treatment of spinal deformity and enhanced respiratory care resulting in far fewer deaths due to pulmonary complications.

Sands et al. showed that young adults with FD reported both mental and physical quality of life within the average range and that their self-esteem improved with age.²⁷ Individuals with FD have married and had families, living far more productive lives than before.

EPIDEMIOLOGY

Paget's disease of bone (PDB), also known as osteitis deformans, is the second most common metabolic bone disease after osteoporosis.^{1,2} Paget's disease of bone was first described by English surgeon Sir James Paget (1814–1899).³ Paget's disease of bone is characterized by enlarged weakened bones that may lead to deformity, fracture, and pain. Paget's disease of bone has a predilection for the axial skeleton.⁴ Paget's disease of bone prevalence varies across human races and locations. In the United Kingdom, the overall prevalence of PDB is estimated to be 2–3.7%^{1,5–7} but occurs rarely in China, Japan, Middle East, India, and Scandinavia.^{8,9} In a South African study, the prevalence of PDB was 1.3% in blacks and 2.4% in whites.¹⁰ Paget's disease of bone is most prevalent not only in the United Kingdom and Western Europe but also in those with British ancestry in Australia, New Zealand, South Africa, North America, and South America.¹¹ A radiographic study from the United States suggested that the prevalence of disease was 1–2% with near equal rates among blacks/whites and sexes.¹² Others have found a slightly higher incidence in males.^{7,12} The risk of PDB increases with age, going from 2% prevalence at age >50 to a 6–10% prevalence at the age of 90 or greater.^{7,13}

There is evidence to suggest that the prevalence of PDB is declining over time^{7,14,15} and that the disease severity is also diminishing.¹⁶ The prevalence of PDB in Britain in

1994 was only 40% of that noted in a prevalence study from 1974, suggesting a possible environmental etiology to this disorder.⁷ Several groups have noted an almost 50% reduction in age and sex-adjusted incidence in the 20 years after initial reports in the 1980s.^{14,16,17} Further, they noted that plasma alkaline phosphatase (ALP) at diagnosis, disease extent on scintiscan, and the numbers of bones involved were diminishing over time.¹⁶

Paget's disease of bone has been identified to be somewhat heritable. Siris et al. found a positive family history in parents or siblings in 12.3% of patients with PDB and only 2.1% of controls. Alternatively said, the rate of Paget's disease was six times higher in relatives of cases than in relatives of controls.¹⁸

Paget's disease of bone can be thought of as being either monostotic or polyostotic, with >60% of cases being polyostotic.^{1,19,20} Monostotic forms affecting the spine are rare, although with the declining severity of disease monostotic spine disease may become more apparent. The spine is the second most common site of involvement for PDB,^{6,21–27} following the pelvis.^{23,27,28} Overall, 35–53% of patients with PDB have spinal involvement.^{20,29,30}

ETIOLOGY/PATHOPHYSIOLOGY

The etiopathology of PDB is an exciting knowledge area, with much new information arising in recent years that has allowed for both genetic and molecular understanding of

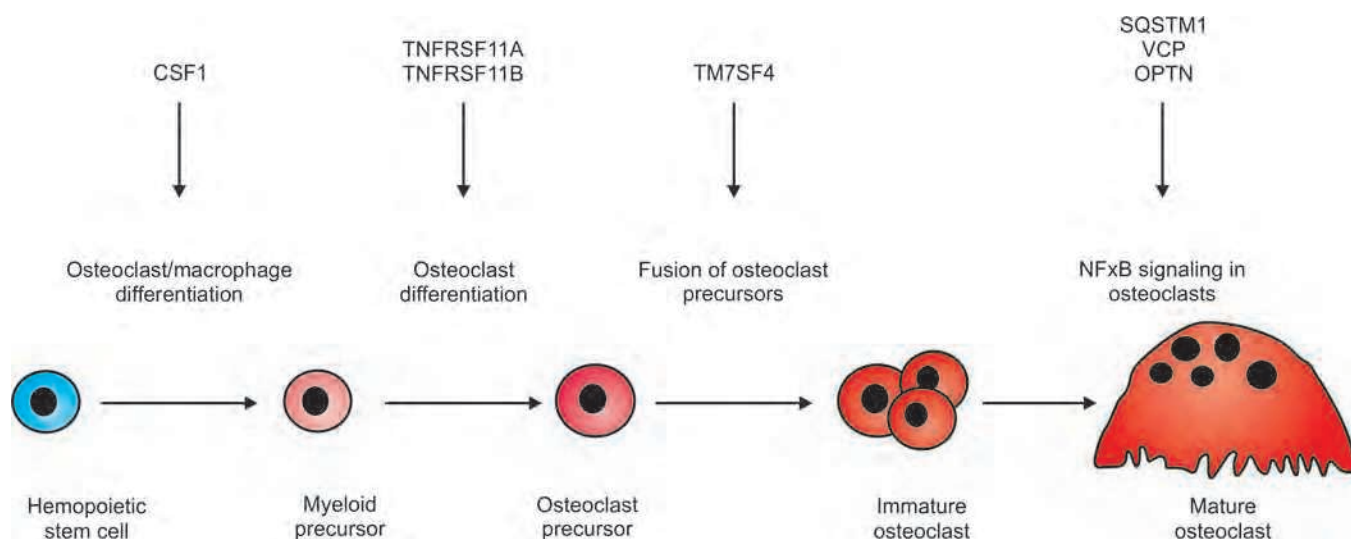

Fig. 27.1: Genes that predispose to PDB play key roles in osteoclast differentiation and function. The CSF1 gene encodes macrophage colony-stimulating factor, which is essential for osteoclast and macrophage differentiation. The TNFRSF11A and TNFRSF11B genes encode RANK and OPG, respectively, both of which play critical roles in osteoclast differentiation and function. The TM7SF4 gene is required for fusion of osteoclast precursors. The SQSTM1, VCP, and OPTN genes all play key roles in the regulation of NFκB signalling and autophagy.

classic histopathological findings. Pagetic bone arises from rapid osteoclastic activity, with subsequent haphazard bone formation, described as a mosaic admixture of woven and lamellar bone and seen particularly well with polarized light.^{5,31} Paget's disease of bone is typically hypervascular, with late marrow fibrosis.^{5,32} Vertebral involvement results in increased bone density, trabecular volume, and vertebral size.^{31,33}

The cellular characteristics of PDB are very different from normal bone, with many fold increases in both osteoclasts and osteoblasts.³¹ Paget's disease of bone is primarily felt to be a disease of osteoclasts that differ from normal by having larger size, being highly multinucleated, and having inclusion bodies.^{34,35}

Classically, PDB has been described in temporal phases with an initial lytic phase, where osteoclastic activity predominates and mimics hyperparathyroidism, leading to an increased ALP.⁶ A mixed phase of osteoblastic repair and ongoing lytic activity follows, with the last pathologic phase consisting of a decrease in bone activity.⁶

While most PDB cases are spontaneously acquired, about 12–15% of cases are familial, passed in an autosomal dominant pattern linked to chromosome 18.^{36,37} Genetic linkage analysis in multiple affected populations has led to an association with sequestosome 1 (SQSTM1/p62);^{38,39} 40–50% of familial PDBs carry mutations of this gene as do 10% of sporadic cases.³⁶ SQSTM1/p62 is felt to be an adaptor protein to *TNF receptor-associated factor*

6, bringing together parts of the RANK/RANKL (receptor activator of nuclear factor-κB ligand) signaling cascade,⁴⁰ which undergoes missense or nonsense mutations in PDB. SQSTM1 mutations, when combined with other genetic markers, may predict the severity and extent of PDB in patients, raising the prospect of personalized risk assessment and early treatment.⁴¹

The central role of the osteoclast in PDB is reinforced through recent genome-wide association studies, identifying several osteoclast maturational and functional genes with relatively large effect sizes.⁴¹ Ralston has illustrated the location of these genes along the osteoclast maturation pathway (Fig. 27.1).⁴²

The presence of inclusion bodies in Pagetic osteoclasts has led to suggestions of the role of Epstein-Barr virus, canine distemper virus, or measles virus (MV) in PDB. Clinical data regarding viral causation are mixed, with reports differing on whether or not viruses can be found, and if so, whether contamination led to the diagnosis.^{42,43} Mouse models of MV proteins overexpressed in osteoclast precursors do seem to create PDB lesions, perhaps underscoring the relevance of the viral theory.⁴⁴

CLINICAL MANIFESTATIONS

Paget's disease of bone may be asymptomatic or alternatively result in pain, deformity, and fracture. Low back pain (LBP) is a common complaint with a prevalence of 27%.²²

Table 27.1: Causes of low back pain.*Causes*

Periosteal stretching
 Vascular engorgement
 Microfractures
 Facet arthritis
 Intervertebral disc disease
 Overt fractures
 Spondylolysis/lithesis
 Sarcoma(rare)

Controversy exists as to whether the LBP is due to PDB primarily or due to degenerative changes. Hadjipavlou found that of those patients with back pain 24% had pain due to PDB alone (pain unrelated to activity and not relieved with rest), 50% due to degenerative changes, and 26% due to a combination of PDB and degenerative changes.⁸ However, Altman et al. have attributed LBP in PDB patients to coexisting osteoarthritis in 88% of cases.^{12,45} Specific causes of LBP in the PDB patient are summarized in Table 27.1.¹

When the spine is affected by PDB secondary neurological symptoms may be present, due to spinal stenosis, in approximately one third of patients. Bony compression by expanding Pagetic bone is thought to be the most common cause of spinal stenosis,²⁴ although other numerous pathological processes have been implicated, including fractures and vascular steal.⁸

The lumbar spine is the most common region of spinal involvement—affected in 58–62% of patients, followed by thoracic spine with cervical spine involvement forming the minority of cases.^{30,31} Involvement of the atlantoaxial region is rare. Lumbar stenosis may lead to radiculopathy and/or neurogenic claudication. When cervical or thoracic disease is present, the resultant stenosis may lead to radiculopathy and/or myelopathy. Myelopathy is more commonly related to thoracic lesions,⁴⁶ likely because of the smaller cross-sectional area of the spinal canal as compared to the cervical region.

Complications related to PDB include pathological fracture and malignant transformation. Spontaneous spinal epidural hematoma, complicating spinal involvement of PDB, has also been reported rarely.⁴⁷ The majority of pathological compression fractures occur in the lumbar spine.⁴⁸ Malignant transformation of PDB is a rare and dreaded complication. In a study of 1,078 asymptomatic and symptomatic patients, eight cases of malignant transformation were identified, yielding an overall incidence of

Table 27.2: Diagnostic imaging features.Plain radiographic features⁵¹

0.7%.⁴⁹ The estimated incidence of Paget sarcoma in those patients with symptomatic PDB is 2–4%.²⁹ Sharma et al. identified 89 patients with secondary sarcoma due to PDB affecting the spine from the Scottish Tumor Registry over a 59-year period. Thirteen cases were available for review. Mean age of these 13 patients was 67 years. There was a preponderance of males and sacral spine involvement. Back pain was the most common presenting feature. Seventy-seven percent of cases were of osteosarcoma. Mean survival of all 13 patients was 4.2 months, unchanged throughout the almost 60-year study period.

DIAGNOSIS

Differential diagnosis of PDB includes metastatic disease, hematopoietic malignancy, metabolic bone disease, primary tumor, and infection. Plain radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) are useful imaging modalities in the diagnosis of PDB. The diagnosis can usually be made by plain radiography.⁵⁰ Characteristic imaging features are summarized in Table 27.2.

Serum ALP is elevated in ~80% of untreated patients with PDB.^{11,50} Serum ALP reflects the severity and extent of disease and therefore may be normal in less active monostotic disease. Serum calcium and phosphorous are usually normal. Asymptomatic patients may be diagnosed with PDB when blood work or radiographs are ordered for unrelated reasons. If there is uncertainty regarding the

diagnosis based on imaging and laboratory studies, a biopsy may be performed to reveal typical Pagetoid histopathology.

Bone scans can be very useful in distinguishing between monostotic and polyostotic forms of the disease. While they can be useful in monitoring response to treatment, the fact that bone scan changes are correlated with serum markers obviates the need for follow-up scans.⁵²

TREATMENT

The treatment of PDB, even when it involves the spine, is first medical. While the indication for a PDB patient's presentation to a spine surgeon's office can vary from pain to neurologic dysfunction, treatment should always begin addressing the underlying pathology. Even if surgery is anticipated, medical treatment can decrease bleeding complications and even improve neurology.⁵³

Medical treatment primarily consists of bisphosphonate treatment. Efficacy of treatment can be monitored with markers of bone formation [serum ALP and N-terminal propeptide of type 1 collagen (P1NP)], and markers of bone resorption (C- and N-terminal telopeptides of type 1 collagen—CTX and NTX).⁵⁴ One can anticipate normalization of ALP levels in 60–90% of patients within 2 months, with subsequent improvement in radiographic and histological parameters.⁵⁴

Initial experience suggested oral treatment for a period of 60 days, with a relapse rate of up to 40% at 2 years.⁵⁵ A short course of treatment potentially avoids bisphosphonate-related complications, such as osteonecrosis of the jaw.^{56,57} Subsequently, a randomized-controlled trial comparing zoledronic acid (5 mg administered intravenously once) versus risedronate (30 mg daily for 60 days) surprisingly showed superior results for the one-time treatment.⁵⁸ Even more, longer term results suggested that biochemical markers remain normal in 99% of zoledronic acid-treated patients, and 87.5% of zoledronic acid patients had clinical success at the late time-point 6.5 years after diagnosis, raising the possibility of cure in PDB.⁵²

Other medications to be contemplated in the medical management include analgesics, nonsteroidal anti-inflammatory drugs, and antineuropathic medications, as dictated by the clinical scenario.³⁶ The RANKL inhibitor denosumab can also be used instead of bisphosphonates when impaired renal function is encountered.⁵⁹

Spinal neurological compressive symptoms are seen and thought to be primarily due to circumferential bony compression. However, a vascular steal syndrome can

also be seen, due to the hypervascularity of the bone, and presumed shunting of some of the spinal cord blood supply.^{60,61} The vascular steal was initially recognized when PDB patients present with neurological signs and normal myelograms, which then responded to calcitonin treatment.^{61,62} Steal phenomenon was then invoked to explain neurological dysfunction after successful decompression or from PDB vertebral fractures. Neurology can improve, after medical management, even without drastic improvement in the imaging findings.⁶³

If medical treatment fails due to a lack of response, or perhaps when the neurological deficit is severe, surgery should be offered. Patients may present acutely with fractures through PDB areas. They are often elderly, harboring other medical comorbidities, with newly diagnosed PDB. Transpedicular biopsy may be necessary to confirm diagnosis, if imaging is not diagnostic. Less invasive techniques, such as laminectomy and kyphoplasty, can be used.^{8,64,65} If spine surgery is anticipated, cardiac function must be evaluated as PDB can cause left ventricular hypertrophy and dysfunction due to a high output cardiac adaptation to increased blood flow.⁶⁶ Cell salvage techniques are also recommended, as Pagetoid bone may bleed profusely.⁵³

CASE PRESENTATION

A 64-year-old man was referred to the outpatient spine clinic with a history of weakness and paresthesias affecting both arms. These symptoms were present and gradually progressed over 4 years. For the previous 4 months, he had difficulty with his hand writing and performing most fine motor tasks. He had a Trendelenburg gait on the right and had been using a cane.

Past medical history included PDB diagnosed in 1989 after right hip fracture that was treated with open reduction and internal fixation. He was not taking any medications. He was operating a hobby farm in his retirement.

He used a cane in his left hand. Without his cane, his gait was unsteady. Tandem gait was not possible. The patient had brisk deep tendon reflexes throughout his upper and lower extremities. He had no Hoffmann reflexes and an equivocal Babinski response but did have sustained ankle clonus bilaterally. His motor power was intact with the exception of the right arm. He had Grade 4 out of 5 weakness throughout the right C5-T1 myotomes. Sensory perception to light touch was intact throughout.

Radiographs of the pelvis revealed end-stage changes related to PDB affecting the pelvis and right femur more

Fig. 27.2: Anteroposterior pelvis depicting widespread cortical thickening, bilateral fusion of the SI joints, deformity of the right femur, and severe bilateral hip arthritis secondary to polyostotic PDB (SI: Sacroiliac; PDB: Paget's disease of bone).

Fig. 27.3: Lateral X-ray lumbar spine: L5/S1 is fused, anterior to posterior enlargement of L4, "picture frame" appearance of L2.

Fig. 27.4: Lateral radiograph: increased density of C2, C3, and C4, anterior-to-posterior vertebral expansion at C5 and C6 with central lucency.

Fig. 27.5: Sagittal CT: mixed lytic and blastic appearance affecting both the anterior and posterior elements at multiple vertebral levels, most notably at C7 (CT: Computed tomography).

than the left femur (Fig. 27.2). Lumbar spine X-rays (Fig. 27.3) depicted characteristic radiographic changes of the spine with increased peripheral sclerosis and central lucency (picture frame vertebra). Plain radiographs of the cervical spine demonstrated multilevel degenerative changes with loss of the normal lordosis and a minimal anterolisthesis of C3 on C4. The C2, C3, and C4 vertebral bodies appeared sclerotic (Fig. 27.4). Computed tomography cervical spine revealed mixed lytic/sclerotic vertebra between C3 and C7 with some involvement of the

posterior elements (Figs. 27.5 and 27.6). Magnetic resonance imaging cervical spine showed severe stenosis at C3/4 secondary to degenerative disc disease and ligamentum flavum hypertrophy with resultant cord compression and myelomalacia (Figs. 27.7 and 27.8).

The patient was diagnosed with cervical myelopathy secondary to cervical stenosis with a secondary diagnosis of PDB affecting the cervical spine. He underwent an uneventful C3/4 anterior cervical discectomy and fusion with partial neurological recovery at 6 months. A histopathological

Fig. 27.6: Axial CT thru T1: coarse trabeculation with enlargement of the pedicles and posterior elements (CT: Computed tomography).

Fig. 27.7: Sagittal MRI: focal central stenosis at C3/4 with myelomalacia. (MRI: Magnetic resonance imaging).

Fig. 27.8: Axial MRI at C3 level: severe central stenosis with effacement of CSF and spinal cord compression (MRI: Magnetic resonance imaging; CSF: Cerebrospinal fluid).

Fig. 27.9: High magnification view of a broad bone trabeculae showing disordered formation. The bone is irregular, with a mosaic pattern typical of later-stage Paget's disease highlighted by haphazard but prominent cement lines. The pattern is reminiscent of a jig-saw puzzle. Some delicate fibrosis of the marrow is also noted. *Source:* Anders KH, Anatomic and General Pathologist, Calgary Lab Services, Calgary, Canada.

specimen from surgery revealed broad trabecular bone formation that was disorganized (Fig. 27.9).

KEY POINTS

- The incidence and severity of PDB is decreasing. There is some evidence that points toward a viral etiology. A minority of cases appear to be inherited in an autosomal dominant manner.
- Pagetic bone arises from rapid osteoclastic activity with subsequent haphazard/disorganized bone formation.

- Clinical presentation may vary from asymptomatic to those having pain, deformity, fracture, or neurological compromise secondary to spinal stenosis.
- Medical management is the mainstay of treatment with spine surgery reserved for fractures and neurological dysfunction that are unresponsive to conservative measures.
- Malignant transformation occurs in <1% of all with PDB and in 2–4% of those with symptomatic PDB.

Snapshot

- » Skeletal Dysplasias
- » Spinal Manifestations of Specific Skeletal Dysplasias
- » Metabolic and Storage Disorders

INTRODUCTION

Spinal disorders associated with skeletal dysplasias and metabolic diseases continue to remain challenging to spine surgeons in view of the relative rarity and unique natural history of these disorders. Early recognition and diagnosis are one of the most important steps in the management of these disorders and often require a multidisciplinary approach including pediatrician, spine surgeon, geneticist, and endocrinologist. Establishing the diagnosis involves a careful analysis of clinical features, family history, relevant imaging, and other diagnostic tests.

SKELETAL DYSPLASIAS

Skeletal dysplasias are systemic derangement of skeletal development involving cartilage and/or bone. Skeletal dysplasias may be classified as osteochondral dysplasias or dysostoses. Osteochondral dysplasias involve the whole skeleton while dysostoses involve only a single group of bones.¹

The initial presentation of these patients is often a screening examination in view of abnormal facial features, limb anomalies, or systemic anomalies. Screening spine radiographs coupled with a detailed physical examination often provide valuable clues to the underlying spinal disorders. Most of these spinal disorders are seen in pediatric or adolescent patients. However, adult spine

Table 28.1: Spinal disorders in common dysplasias.

<i>Dysplasia disorder</i>	<i>Spinal disorder</i>
Achondroplasia	Foramen magnum stenosis Spinal stenosis Thoracolumbar kyphosis Lumbosacral hyperlordosis
Diastrophic dysplasia	Cervical kyphosis Scoliosis Thoracic hyperkyphosis
Spondyloepiphyseal dysplasia (SED) tarda	Platyspondyly Disc herniation
SED congenita	Odontoid hypoplasia Atlantoaxial instability
Pseudoachondroplasia	Atlantoaxial instability Scoliosis

surgeons also encounter dysplastic patients with varying degrees of spinal deformities, disc herniation, or spinal stenosis. Spinal manifestations of skeletal dysplasias commonly include but are not limited to instability, deformities, stenosis, fractures, neural compression, or a combination of any of these^{2,3} (Table 28.1).

Instability of the cervical spine usually occurs at the atlantoaxial junction and less commonly at the occipitocervical junction in patients with dysplasia. Instability may occur because of bony abnormalities ranging from hypoplasia to developmental failure and/or abnormal

ossification of the cervical vertebrae, associated odontoid hypoplasia, poor ligamentous fixation of C2 resulting in C1-2 subluxation, abnormal development of the posterior processes, or ligamentous laxity.²⁻⁴ Skeletal dysplasias commonly associated with significant instability of C1-2 region include congenital SED, Kniest dysplasia, SMD, chondrodysplasia punctate, DD, and pseudoachondroplasia.^{2,3}

Periodic neurologic evaluation coupled with cervical spine radiographs should be obtained in these patients to detect early signs of instability. Flexion-extension radiographs and MRI can also be done in doubtful cases of instability.⁵

Scoliosis deformity in skeletal dysplasias is common in SED dysplasia, CDP, and DD.^{6,7} Progression of deformity in these cases may mimic the rapidly progressing congenital (dysplastic) curves or slowly progressing idiopathic type curves.^{6,7}

Sagittal plane deformities can affect any region of the spine. Thoracolumbar kyphosis is very common in achondroplasia. Lumbar spine involvement in the form of a gibbus occurs in achondroplasia.⁸ Cervical kyphosis or hyperlordosis is a very common feature of DD.⁹

Management of spinal disorders in patients with skeletal dysplasia involves careful evaluation of other skeletal anomalies, especially leg deformities, limb length inequality, and pelvic obliquity. The overall functional status of the patient with regards to ambulation and sitting balance should always be considered while formulating a treatment plan.

Surgical management of these patients is challenging to the anesthesia providers as well.¹⁰⁻¹² A detailed preoperative evaluation should always take into consideration possible difficult venous/arterial line access, difficult intubation, difficult positioning, comorbidities, abnormal chest cavity, and compromised pulmonary function.¹³ The positioning of the patient on the surgical table may require special table extension and padding equipment in view of abnormal shape and body structure.

Parents of the affected children need to be counseled in detail about the disease process and the natural history of the disorder. Evaluation of siblings to detect spinal anomalies is important as is the need for genetic counseling regarding future children.¹⁴⁻¹⁶

SPINAL MANIFESTATIONS OF SPECIFIC SKELETAL DYSPLASIAS

Achondroplasia: It is the most common nonfatal skeletal dysplasia, with an incidence of 1 in 10,000 to 1 in 30,000.^{17,18}

It is characterized by short stature (shortening of trunk with short extremities in rhizomelic pattern), frontal bossing, midface hypoplasia, normal cognitive development, and a varying degree of musculoskeletal manifestations.

Achondroplasia is caused by mutations of gene encoding fibroblast growth factor receptor-3 (FGFR3) on the short arm of chromosome 4.¹⁷ This mutation results in substitution of arginine for glycine for FGFR-3 at the physal cartilage. This mutation results in abnormal endochondral ossification of the long bones and spine, which clinically manifests as short extremities and a short trunk. It is transmitted as an autosomal dominant disorder with full penetrance. However, new mutations play a significant role in transmission, as 85% of babies with achondroplasia are born to normal parents.

The short stature is generally evident at birth or early childhood with a rhizomelic limb shortening (proximal limbs affected more than distal). Foramen magnum stenosis is usually the earliest manifestation with regard to the spine. Other spinal manifestations, which include thoracolumbar kyphosis, lumbar hyperlordosis, and spinal stenosis, may not become clinically significant until late adolescence or adulthood.

Foramen magnum stenosis: Defective endochondral bone formation at the cranial base and craniocervical junction results in a small foramen magnum, a short basicranium and clivus, a shallow posterior fossa with a horizontally oriented inferior occiput, an abnormal odontoid process, and a narrow upper cervical canal.¹ Stenosis at the foramen magnum is present in 5–10% of patients with achondroplasia, and can present with a myriad of features including those suggestive of airway compression (respiratory difficulty or apnea) or brainstem compression (apnea, lower cranial nerve involvement, hyperreflexia, paresis, or clonus). Cervicomedullary compression can be classified into severe and mild types based on the ratios of the brainstem diameter at the foramen magnum, the site of the most severe stenosis to the diameter at the pontomedullary junction, and C3 level.¹⁹

The American Academy of Pediatrics recommends screening for foramen magnum stenosis with polysomnography and computed tomography or MRI in all infants with achondroplasia.²⁰

Surgical decompression of the cervicomedullary junction is indicated in cases of severe or symptomatic cases. Bagley et al.²¹ studied the results of 46 cervicomedullary decompressions over a period of 11 years in pediatric patients with heterozygous achondroplasia and foramen magnum stenosis and reported complete resolution or

Figs. 28.1A to C: (A) Posteroanterior (PA) and (B and C) lateral radiographs of a patient with achondroplasia. The PA demonstrates narrow interpedicular distance. The lateral images demonstrate a progressive focal kyphosis deformity secondary to wedged body and short pedicle length.

partial improvement in the preoperative symptoms in all patients after surgical decompression. Cerebrospinal fluid (CSF) leak was the common complication with no other significant morbidity in their series.

Spinal stenosis: Stenosis of the spine is a very common feature of achondroplasia and can affect any region of the spine. The lumbar and cervical spines are the most common site of affliction. Stenosis is attributed to the abnormal endochondral ossification and premature fusion leading to small vertebral bodies and short (anterior to posterior) thick pedicles with narrow interpedicular distance (Fig. 28.1A). Clinically symptomatic stenosis usually occurs later in adulthood after the superimposition of degeneration. Clinical features of stenosis are present in up to 50% of adult patients.¹⁷

The indications for surgical decompression include progressive symptoms, urinary retention, significant claudication, and failure of conservative treatment.²² The surgical options include decompression by laminectomy with or without instrumentation and fusion. Carlisle et al.²³ analyzed the impact of timing of laminectomy procedures on symptom resolution in their study of 49 patients and reported a better outcome, if surgery was done early. The best results were noted, if the procedure was done within 6 months of onset of symptoms.

Laminectomy without fusion, however, has been reported to increase the chances of progression of kyphosis in immature patients.²⁴ Baca et al.²⁵ in their review of 18 immature patients with achondroplasia, reported a 3.5

times higher chance of revision surgery in uninstrumented decompressions and concluded that surgical decompression with instrumentation significantly reduces the symptoms and the likelihood of revision surgery in children.

Thoracolumbar kyphosis: Most of the children with achondroplasia have a rounded back in early infancy because of hypotonia.¹⁷ It gradually improves with age in most of the patients as they gain muscle function and tone before the true fixed kyphosis establishes itself. In a systematic review of seven studies, Engberts et al.²⁶ reported a prevalence of 50–100% thoracolumbar kyphosis in patients with achondroplasia. However, the true prevalence could not be determined because of heterogeneity of the population.

Thoracolumbar kyphosis (Fig. 28.1B) increases with hypotonia, delayed motor development, an initial measurement of $>25^\circ$, percentage of apical vertebral wedging for the height of the vertebra, and apical vertebral translation.²⁷ Persistent kyphosis has been reported to increase the risk of spinal stenosis, progression to fixed deformity,²⁸ hip flexion contracture, and lumbar hyperlordosis.²²

Pauli et al.²⁹ reported good success in preventing the development of severe kyphosis in their study of 66 kids with achondroplasia. They advocate a protocol of inhibition of unsupported sitting in early age and brace application in older children. No patient developed progressive kyphosis in their series. Siebens et al.³⁰ also reported partial correction of kyphosis in 17 pediatric patients who wore a brace. Their study also reported symptomatic relief

from back pain and neurological complaints using a brace in 31 children and adults.

Surgical correction of kyphosis is indicated in cases of kyphosis progression despite bracing, with neurological compromise (secondary to stenosis) or with kyphosis of $>50^\circ$.²² Various surgical strategies for fusion (posterior, combined anterior/posterior with anterior or posterior instrumentation, and uninstrumented fusion) have been described.^{22,31}

Ain et al.³¹ reported a series of four patients who underwent fusion using the combined anterior/posterior (two stage) instrumented fusion without any neurological complications. All patients achieved fusion in their series. Another series by Ain and Browne³² reported 100% fusion rate in patients with combined anterior/posterior (five patients) or posterior-only (seven patients) approach. Kyphosis corrected in about 50% of their patients. The complications included two cases of implant failure and one case of CSF leak.

Lumbosacral hyperlordosis: It is a very common feature of achondroplasia. It is caused by anterior pelvic tilt and the repeated squatting in case of claudicating stenosis. This leads to a protuberant belly and hip flexion contracture.²²

Femoral lengthening has been shown by Park et al.³³ to improve the hyperlordosis of the sacrum without significantly affecting the lumbar lordosis in three patients. Similar results have been reported by Vilarrubias et al.³⁴ The correction of sacral hyperlordosis is attributed to the correction of underlying pelvic femoral muscle imbalance and the resultant sacral tilt.^{33,34}

Pedicle screws are generally a safe fixation modality. However, instrumentation in these patients requires special attention in view of unique anatomical features: smaller pedicles, progressively divergent pedicles, more lateral entry points in the distal lumbar spine, and the cranial inclination of pedicles. The pedicles show a shortened anteroposterior diameter (Fig. 28.1C), and the posterior aspect of the vertebral bodies is concave. The interpedicular distances narrow progressively from the upper to the lower lumbar spine.³⁵

Diastrophic dysplasia: It is a recessively inherited skeletal dysplasia caused by irregular chondrocyte distribution at the growth plate and fibrocystic changes in the matrix. There is wide variation in the phenotype including a lethal neonatal form and the classic nonlethal forms. Rhizomelic short stature and equinovarus foot deformities are noted at birth, but sagittal or coronal spinal deformities (scoliosis, lumbar hyperlordosis, and cervical kyphosis), hitchhiker's

thumb, other deformities of the large joints, and early-onset osteoarthritis appear later.³⁶

Prenatal diagnosis for pregnancies at increased risk is possible by ultrasound examination early in pregnancy or by molecular genetic testing.^{14,37}

Cervical kyphosis: Since cervical kyphosis is already evident in some of the neonates with DD, it seems to develop prenatally. Cervical kyphosis in these patients may spontaneously resolve or progress. Remes et al.⁹ outlined the pathophysiological findings and factors associated with progression of kyphosis: angle $>60^\circ$, severe hypoplasia in C3–C4, wedge-shaped vertebral body, pathological loading of cartilaginous parts in the vertebrae, and extensor-flexor muscle imbalance. They reported the natural history of cervical kyphosis in 120 patients with DD. Of these 120 patients, 29 (24%) were noted to have kyphosis; in 25 patients, the first radiographs were taken before the age of 18 months, and 24 (96%) had cervical kyphosis. Most of the kyphosis in their series resolved spontaneously by 7 years of age. However, they noted severe, rapid progression of deformity in cases that did not resolve. The deformities need to be followed closely, as these progress very rapidly and can prove fatal.⁹

The indications for surgical stabilization and decompression include severe, progressive deformity, and neurological symptoms. Combined anterior/posterior fusion is reported to be better in these patients.⁹

Scoliosis: It is a common feature in patients with DD, with an incidence of 37–88%.^{6,38} Most of the deformities do not progress significantly; however, patients who present very early in childhood with severe deformities tend to progress rapidly.⁶ Remes et al.⁶ reported an incidence of scoliosis in 88% of cases (86 out of 98 patients) in a major series of patients with DD. They also proposed a classification for scoliosis in DD based on progression: early progressive, idiopathic-like, and mild nonprogressive. The early progressive type resembles infantile progressive idiopathic scoliosis with regard to early onset, rapid progression, and severe deformity manifestation. Mild, nonprogressive types can be easily distinguished and followed. Idiopathic types behave similar to idiopathic juvenile or adolescent curves and can be treated as per the individual curve progression. This classification system is proposed as a good tool for predicting natural history of scoliosis in DD and for adjusting the timing of surgery in individual patients.

Early progressive curves require early fusion, as these curves tend to progress very rapidly. Both combined anterior/posterior and posterior-only fusion have been

suggested.³⁹ Matsuyama et al.³⁹ reported the outcome of surgical arthrodesis for scoliosis in 21 patients with DD. Four were managed with posterior-only fusion; pseudarthrosis requiring revision surgery developed in two out of these four patients. Combined anterior and posterior procedures achieved better fusion.

Thoracic kyphosis: Thoracic hyperkyphosis is a very common feature of DD and is associated with scoliosis. The apex of the kyphosis is usually at the junction of the thoracic and lumbar scoliosis curves. The kyphosis is reported to progress very rapidly and necessitates early intervention to prevent catastrophic deformity.³⁹

In the same series, Matsuyama et al.³⁹ reported 15 cases of hyperkyphosis in 21 patients with DD. The average correction was 21° (0°–62°), with fusion achieved in 15 patients. The kyphosis correction was preserved at follow-up. The aim of the surgery was to prevent the progression of the curves as opposed to actually achieving deformity correction.³⁹

Spondyloepiphyseal dysplasia: It is characterized by abnormal growth of the spinal vertebrae and epiphysis leading to short-trunk dwarfism with shortened proximal and middle limbs and relative sparing of hands and feet.¹ There are two different types of SED: SED tarda and SED congenita.

I. **Spondyloepiphyseal dysplasia tarda:** It is an X-linked recessive disorder caused by abnormal type II collagen. It is characterized by short stature resulting from platyspondyly (humping and eburnation of the central and posterior part of the end plates) and progressive arthropathy. The epiphyses in the long bones are dysplastic, especially in the proximal parts of the limbs. Precocious arthritis develops in the hips as well as in the spine.⁴⁰

This disorder may cause a predisposition to multiple thoracic disc herniation,⁴¹ which may rarely lead to spastic paraplegia.⁴² No other significant symptomatic affliction of the spine has been reported with this disorder.

II. **Spondyloepiphyseal dysplasia congenita:** It is an autosomal dominant disorder. It is the more severe form of the disorder and is commonly associated with serious spinal abnormalities in children. The prominent recognizable feature present at birth is cleft palate. Also, eye involvement is common in the form of high-grade myopia and retinal detachment. The other common features include short neck, pectus carinatum, and barrel-shaped chest.

The vertebral bodies are irregular and flat with narrow disc spaces, small sagittal atlas diameter, odontoid hypoplasia, loose or lax ligaments, and atlantoaxial subluxation.

Atlantoaxial instability associated with odontoid hypoplasia or ligamentous laxity is the most common spinal manifestation of SED congenita in children. Myelopathy can present clinically in various degrees of neural deficit including paralysis and potentially serious respiratory complications. Instability has been reported to progress with age and increasing atlantodental interval (ADI).^{1,43} Most of the patients with myelopathy have been reported to have an ADI >5 mm.⁴⁴ Sagittal canal diameter of <10 mm at the level of the atlas is associated with severe cord compression.^{43,44} Stabilization of the atlantoaxial region with or without decompression is indicated in symptomatic patients with severely stenotic deformity.¹ Miyoshi et al.⁴³ reported the surgical outcome of reduction and stabilization in seven out of 29 patients with SED of which six underwent surgery for myelopathy. C1 laminectomy was required in all of their cases to achieve satisfactory reduction. Ain et al.⁴⁵ reported a successful fusion in six out of seven patients with SED with no other significant complications. Four of their patients with neurological symptoms improved after fusion.

Pseudoachondroplasia: It is a form of short limb dwarfism characterized by involvement of both epiphyses and metaphysis. Skeletal manifestations involve marked joint laxity and instability leading to severe premature osteoarthritis. Two autosomal dominant (mild) and two recessive (more severe) variants of pseudoachondroplasia have been described.

The long bones show marked flaring and irregularity of metaphyses with delayed maturation of epiphyses, which are small and irregular. Maturation is significantly delayed in the triradiate cartilage and entire acetabulum.⁴⁶ Spine radiographs show anterior beaking of vertebrae and/or platyspondyly. Odontoid hypoplasia, a very common feature, leads to upper cervical spine instability that increases with the age.

Shetty et al.⁴⁷ studied the upper cervical spine in 15 patients with pseudoachondroplasia. Os odontoidum (incomplete fusion of the os odontoid process to the body of the axis) was present in 60% of their patients. Radiological evidence of os odontoidum and atlantoaxial instability did not warrant surgery in their study, as no signs of cervical myelopathy developed or progressed in their patients during the follow-up period. However, this study emphasized the need for regular clinical and radiological

evaluation to detect early signs of neurological involvement. Ain et al.⁴⁵ reported successful fusion for upper cervical instability in five patients with pseudoachondroplasia. One of their patients developed instability below the fused segment with a worsening of neurologic status.

Mild thoracic or thoracolumbar scoliosis is common in these patients, as is mild spinal stenosis.

Kniest syndrome: It is a disorder of type II collagen characterized by short stature as well as severe ophthalmic involvement including retinal detachment, cataracts, and visual loss. Musculoskeletal features include short limbs with enlarged and stiff peripheral joints. Radiographic features include platyspondyly, hypoplastic femoral head, and enlarged epiphysis of long bones with cloud-like calcification.⁴⁸

Atlantoaxial instability similar to other common dysplastic syndromes has been reported⁴⁹ and requires periodic clinical and radiographic evaluation. Stabilization is indicated in cases of neurological involvement or severe instability. Ain et al.⁴⁵ in their series of 25 patients with skeletal dysplasias, reported two patients with Kniest syndrome who underwent successful atlanto-occipital fusion. Spine deformities do not progress much, because the trunk is stiff. Scoliosis is generally mild and does not usually require treatment.

Metatropic dysplasia (MD): It is a rare skeletal dysplasia caused by a mutation in the *VDRL4* gene leading to abnormal endochondral ossification. The phenotypic variability of MD has led to a classification based on radiological anomalies dividing into three different types: a lethal autosomal recessive form, an autosomal recessive nonlethal form, and a nonlethal autosomal dominant form with less severe radiographic manifestations and a better clinical outcome.

Characteristic abnormalities include tubular bones with short diaphyses and wide metaphyses (dumbbell-like configuration) of long bones, delayed ossification of the ischiopubic bone, platyspondyly, precocious calcification of hyoid and cricoid cartilage, and irregular and squared-off calcaneal bones.⁵⁰

The main spinal manifestation is progressive kyphoscoliosis, which develops early and usually requires surgical intervention by preadolescence. The scoliosis tends to progress and becomes rigid in untreated patients.⁵¹ Another spinal manifestation is compression of the cervical spinal cord by foramen magnum stenosis and atlantoaxial instability. Spinal fusion with or without decompression is indicated for radiologically proven atlantoaxial instability.⁵²

Thanatophoric dysplasia: It is an uncommon dysplasia characterized by significant involvement of the base of the skull, spine, ribs, and appendicular long bones. Malformations of the vertebral laminae, most prominent in the basiocciput and atlas vertebra, lead to compression of the cervical spinal cord. Stenosis of the foramen magnum and spinal canal may contribute to the ventilatory insufficiency that often causes death in these patients.⁵³

Chondrodysplasia punctata: It is a rare skeletal dysplasia characterized by stippled epiphyses during infancy. It is caused by arylsulfatase (ARS) E deficiency. Although the symptoms are usually mild, severe spinal cord compression by dysplastic vertebrae may develop.

Mason et al.⁷ identified three patterns of spinal involvement in their series of 20 patients: cervical bony disruption; a slowly progressive, nondysplastic scoliosis responding well to standard fusion techniques; and a dysplastic kyphoscoliosis, which is rapidly progressive and resistant to fusion. Dysplastic scoliosis may require multiple surgical procedures. The best results in dysplastic curves are reported with an anterior strut graft and a posterior fusion.⁷

Campomelic dysplasia: It is a rare autosomal dominant skeletal dysplasia classically characterized by bent bones of the extremities, tracheobronchial narrowing, thoracic kyphoscoliosis (Figs. 28.2A to D), and various degrees of phenotypic sex reversal. Incomplete ossification of the cervical vertebral pedicles results in congenital cervical instability and kyphosis.⁵⁴ The late ossification of the midthoracic pedicles is a characteristic radiologic feature.

Coscia et al.⁵⁵ advocated aggressive treatment of spinal deformities in their series of eight patients. Vertebral body hypoplasia is reported to be the cause of deformities that include scoliosis, thoracic hyperkyphosis, and cervical kyphosis.

Spondylometaphyseal dysplasia: It is a group of skeletal dysplasias that principally involve the spine and the metaphyses of long bones. It is characterized by short stature, developmental coxa vara, fragmented appearance of the metaphysis (corner fractures), abnormally shaped vertebrae, and odontoid hypoplasia.⁵⁶ Spinal deformities, including scoliosis, kyphosis, and cervicomedullary instability, have been reported in this rare dysplastic disorder.

Spondyloepimetaphyseal dysplasia: It is a rare skeletal dysplasia frequently associated with severe spinal deformity. The orthopedic manifestations can include hypoplastic odontoid with atlantoaxial instability, severe kyphosis or lordosis of the dorsal and lumbar spine, hip subluxation,

Figs. 28.2A to D: Spine radiographs of a patient with campomelic dysplasia showing severe early onset kyphoscoliosis (A and B) before and (C and D) after application of VEPTR (vertical expandable prosthetic titanium rib) device.

Table 28.2: Common spinal involvement in mucopolysaccharidosis (MPS).

<i>MPS</i>	<i>Enzyme deficiency</i>	<i>Spinal disorder</i>
MPS IVA (Morquio syndrome)	N-acetyl-galactosamine-6-sulfate sulfatase	Odontoid hypoplasia Atlantoaxial instability Spinal canal stenosis Cord compression Thoracolumbar kyphosis
MPS I (Hurler syndrome)	α -L-iduronidase	Odontoid hypoplasia Atlantoaxial instability Thoracolumbar kyphosis/scoliosis
MPS II (Hunter syndrome)	Iduronate-2-sulfatase	Cervical myelopathy Atlantoaxial instability Gibbus
MPS VI (Maroteaux-Lamy syndrome)	Arylsulfatase B	Thoracolumbar gibbus

coxa vara, genu valgum, club foot, and early severe hip osteoarthritis.⁵⁷ These deformities, which can appear early in life, progress rapidly and are potentially fatal.

METABOLIC AND STORAGE DISORDERS

Mucopolysaccharidoses and mucolipidoses are inborn storage diseases, caused by deficiency of lysosomal degradation enzyme. Musculoskeletal manifestations are attributable to intracellular accumulation of undegraded substrates within the lysosomes of chondrocytes, the extracellular matrix of articular cartilage, and synovium⁵⁸ (Table 28.2). Most of these disorders are transmitted in an autosomal recessive pattern with the exception Hunter's syndrome, which is X-linked recessive.⁵⁹

Most children with MPS are born with very few distinguishing features, including coarsened facial features such as fullness of the skin, full eyebrows, enlarged tongue, retained epicanthal folds, and short neck and do not manifest any significant growth or development issues in the 1st year or more of life.⁵⁸

Cervical spine involvement in the form of atlantoaxial instability and odontoid hypoplasia is a common feature of lysosomal storage disorders like Morquio, Maroteaux-Lamy, and Hurler syndromes.⁶⁰ Atlantoaxial instability and odontoid hypoplasia can lead to severe neurological impairment and death. Spinal stenosis is the result of a complex interplay of glycosaminoglycan (GAG) accumulation behind the odontoid process, dural thickening, and C1 ring hypoplasia. The accumulation of soft tissue results in progressive stenosis and compression of the spinal cord

at the occipitocervical junction. Significant instability (>8 mm) and cord signal change on MRI are indications for surgical stabilization.⁵⁸

Acute thoracolumbar kyphosis is a classic gibbus deformity and a common radiographic finding in patients with MPS. Levin et al.⁸ studied the lumbar gibbus in storage disorders and reported that all patients had localized gibbus of the upper lumbar spine, characterized by anterior wedging and posterior displacement of the vertebrae at the apex of the curve, producing a beaked appearance. The curve is generally at or below the conus and is most severe in patients with MPS-IV. Neurologic complications are unusual in these patients. Continued progression $>70^\circ$ or myelopathy are indications for fusion, which is generally combined anterior and posterior in most of these patients.⁵⁸

Some of the more common storage disorders that affect the spine are briefly described here.

Morquio syndrome (MPS IVA): It is a lysosomal storage disorder caused by a deficiency of the enzyme N-acetylgalactosamine-6-sulfate sulfatase, causing progressive accumulation of keratan sulfate (KS) and chondroitin 6 sulfate (C6S) in tissues. Because KS and C6S are major components of proteoglycans in cartilage and bone, MPS IVA mainly manifests as skeletal dysplasia and short stature. Mucopolysaccharidosis IVA is multisystemic but manifests primarily as a progressive skeletal dysplasia, especially involving the spine.^{58,61}

Significant phenotypic variations can vary from very mild to severe. The onset of symptoms typically occurs prior to 1 year of age in rapidly progressing patients and generally in the second decade of life in slowly progressing patients. Severe phenotype may be associated with death in the second or third decade caused by paralysis from cervical myelopathy, respiratory insufficiency, and heart abnormalities.

Spinal involvement in MPS IVA occurs at two distinct sites. Cervical spinal involvement, particularly instability and compression at the C1–C2 level, is a near universal finding and predisposes patients to myelopathy, paralysis, and sudden death.⁶² Spinal cord compression due to kyphotic deformity at the thoracolumbar level is not as common but can lead to paraplegia with insidious onset.

Cervical spine subluxation and instability: Cervical spinal involvement, particularly instability and compression at the C1–C2 level, is thought to arise from a combination of dens hypoplasia and ligamentous laxity. Cervical instability is pathologic in MPS when the ADI is >5 mm at any age or there is a difference of >2 mm in ADI on flexion–extension lateral radiographs.⁶¹

Solanki et al.,⁶³ in their MRI evaluation of the spine in MPS-IV, suggested that the spine is narrower at C1–2, appearing as an inverted funnel shape. The sagittal diameter and axial surface area of both the spinal canal and cord are reduced.⁶³

Indications for surgery include the development of pathologic reflexes and neurological deficits with instability on neurological examination. Foramen magnum decompression is indicated in cases of associated compression at the foramen magnum. Posterior occipitocervical fixation and fusion with instrumentation and bone graft is the most recommended approach.^{49,63} Ain et al.⁴⁵ analyzed the outcome of occipitocervical fusion in seven patients with MPS IV, all of whom underwent successful fusion. Five of these seven patients had neurological symptoms secondary to instability, and in all except one patient the neurological symptoms resolved after fusion.

Spinal canal stenosis and cord compression: Generalized thickening of the posterior longitudinal ligament and the ligamentum flavum due to GAG deposition is the prime etiological factor for spinal stenosis. The stenosis along with cervical instability, cartilaginous and ligamentous hypertrophy at the atlantoaxial joint, disc protrusion, and thoracolumbar kyphosis can cause diffuse cord compression.⁶¹

Evidence of cord compression with signal change on MRI even without symptoms is an indication for decompression and stabilization surgery. Combined anteroposterior fusion in association with anterior discectomy is highly recommended.

Regular neurological and radiological monitoring is strongly recommended to ensure early detection of instability or cord compression.

Typical problems with anesthesia in MPS-1 include airway obstruction, intubation difficulties or failure, possible emergency tracheostomy, and cardiovascular and cervical spine issues.⁶⁴

Mucopolysaccharidosis type I (MPS I) (Hurler syndrome): It is a chronic, progressive, multisystemic lysosomal disease caused by a deficiency of α -L-iduronidase enzyme. Mucopolysaccharidosis I is commonly classified into three clinical syndromes: Hurler, Hurler-Scheie, and Scheie. Hurler syndrome is the most severe phenotypic form and is described below.

The most common manifestations of MPS I include a characteristic facies, corneal clouding, macroglossia, hearing loss, hydrocephaly, cardiopathy, respiratory problems, hepatosplenomegaly, inguinal and umbilical hernia, dysostosis multiplex, limited joint mobility, and cognitive

Figs. 28.3A and B: Hurler's syndrome. (A) Prominent thoracolumbar kyphosis secondary to the wedged vertebral body. (B) Post-operative images after surgical correction via a posterior-based vertebra resection and stabilization with an anterior cage and posterior screws and hook construct.

impairment. The symptoms arise after birth and progress rapidly. Untreated patients have a very high mortality rate in the first decade of life due to complications related to brain damage or cardiorespiratory problems.⁶⁵

- **Spinal involvement:** Accumulation of GAGs in paraspinal ligaments increases the potential for morbidity, resulting in major risks to the cervical column. Odontoid hypoplasia is a common feature in these patients and predisposes to instability and subluxation at the cervicomedullary region. Deformities in the form of thoracic kyphosis⁶⁶ (Figs. 28.3A and B) and thoracic/lumbar scoliosis are also common.

Tandon et al.⁶⁷ described the spinal problems in 12 patients with this disorder. Kyphosis in proximal lumbar region was the most common spinal affection in their study. The other spinal manifestations included odontoid hypoplasia and thoracic scoliosis. Neurological problems were reported in two of their patients.

In a review of MPS I, van der Linden et al.⁶⁶ reported musculoskeletal problems in 399 patients. The most frequent musculoskeletal abnormalities reported in their study included odontoid hypoplasia (72%), thoracolumbar kyphosis (81%), genu valgum (70%), hip dysplasia (90%), and carpal tunnel syndrome (63%).

Bone marrow transplantation has increased the survival of these patients, but musculoskeletal manifestations seem largely unresponsive to hematopoietic stem cell transplantation.^{66,68}

Mucopolysaccharidosis type II (MSP II) (Hunter syndrome): It is a rare genetic disease caused by deficiency of the lysosomal enzyme iduronate-2-sulfatase. Mucopolysaccharidosis II is the only MPS with X-linked inheritance. Common causes of death, which usually occurs within the second decade of life, are obstructive airway disease and cardiac failure due to valvular dysfunction, pulmonary hypertension, and myocardial disease.

Accumulated GAGs in joints and connective tissue lead to significant skeletal deformities including spastic paresis due to cord compression at the craniocervical region, vertebral and rib abnormalities, pelvic dysplasia, severe hip disease, and joint contractures.

Spinal cord compression/cervical myelopathy: GAG accumulation in the spinal meninges leads to spinal cord compression. Clinically, patients may present with quadriplegia and/or spasticity. Gibbus deformity and/or atlantoaxial subluxation may aggravate spinal canal stenosis.

Other neurological complaints suggestive of spinal cord compression include urinary retention secondary to neurogenic bladder. Surgical decompression in MPS II is required, and in order to achieve a satisfying outcome, it may be crucial to perform surgery at an early stage of the disease.⁶⁹

Mucopolysaccharidosis type VI (Maroteaux-Lamy syndrome): It is a rare autosomal recessive genetic disease caused by deficiency of the enzyme *N*-acetylgalactosamine-4-sulfatase or ARSB.

Patients with MPS VI exhibit a chronic and progressive course, where primarily the skeletal and cardiopulmonary systems, cornea, skin, liver, spleen, brain, and meninges are affected. In general, patients have a short trunk and a thoracolumbar gibbus.

Most of the individuals with MPS VI progress to death in their second or third decade of life as a result of heart failure.

Mucopolipidosis: I-cell (mucopolipidosis 2) is a rare, autosomal recessive neurodegenerative lysosomal storage disease. Neonatal skeletal radiographs have features resembling hyperparathyroidism and rickets, and are present during the 1st year of life. Prominent radiographic findings include a butterfly vertebral body and irregular epiphyseal ossification.⁷⁰

SUMMARY

Spinal disorders associated with dysplasias and metabolic disorders continue to remain challenging despite recent advances in diagnostic imaging and spinal instrumentation systems. The principle of treatment in these disorders remains the same: early recognition and stabilization of

neurologically unstable or potentially fatal unstable segments, preventing significant progression of deformities, and ensuring a good quality of life. These patients often need multidisciplinary care in view of the systemic involvement and comorbidities.

KEY POINTS

- Early recognition and diagnosis are one of the most important steps in the management of skeletal dysplasias and associated spinal disorders.
- Periodic neurologic evaluation along with cervical spine radiographs should be done in most patients with skeletal dysplasias to detect early signs of atlantoaxial instability. Flexion-extension radiographs and magnetic resonance imaging (MRI) can also be done in uncertain cases of instability. Common dysplasias associated with instability include congenital spondyloepiphyseal dysplasia (SED), Kniest dysplasia, spondylometaphyseal dysplasia (SMD), chondrodysplasia punctata (CDP), diastrophic dysplasia (DD), and pseudoachondroplasia.
- Achondroplasia is the most common nonfatal skeletal dysplasia. Foramen magnum stenosis is usually the earliest manifestation with regards to the spine. Other spinal manifestations include thoracolumbar kyphosis, lumbar hyperlordosis, and spinal stenosis associated with shortened pedicles. Stenosis may present in late adolescence or adulthood.
- Atlantoaxial instability is the most common spinal manifestation in SED congenita. Myelopathy can cause neural deficits including paralysis and potentially serious respiratory complications. Stabilization of the atlantoaxial region with or without decompression is indicated in symptomatic patients with severe stenosis.
- The upper cervical spine is involved in mucopolysaccharidosis (MPS) IV, MPS I, and MPS VI. Significant instability and cord signal change on MRI are indications for surgical stabilization.

Operative and Nonoperative Management of Rheumatoid Arthritis

Jeremey Reynolds, Christopher Brown

Snapshot

» Diagnostic Challenges

INTRODUCTION

Incidence

Rheumatoid arthritis is a chronic inflammatory condition of unknown etiology predominantly affecting synovial joints, but with the potential for numerous systemic manifestations. It is more common in women¹ and in middle age.² One study suggested that the lifetime risk of developing rheumatoid arthritis may be as high as 3.6% of women and 1.7% of men in the United States.¹ The spine is commonly affected; the cervical spine being involved in ~40% of patients.³ These patients are at risk of cervical myelopathy, progressive neurological damage, and death.⁴ Interestingly, while hospitalization for other severe manifestations of rheumatoid arthritis has decreased significantly in recent years, this does not appear to be true for rheumatoid cervical myelopathy.⁵

Pathology

Inflammation in rheumatoid arthritis has a predilection for synovial joints. The typical presentation is with a symmetrical arthritis affecting the small joints of the hands and the feet. Histologically, there is a thickened synovium with increased vascularity and cellularity, in particular T cells, macrophages, and plasma cells. Joint destruction, instability, and deformity are thought to result from the formation of an inflammatory pannus that adheres to the articular cartilage and produces proteinases, destroying first cartilage and then bone.⁶

Spinal Manifestations

At its most severe, erosion of bone and ligamentous structures in the spine can lead to instability and devastating neurological consequences. The most common manifestation of rheumatoid spinal disease is anterior atlantoaxial subluxation, occurring in ~14% to 23% of patients.^{7,8} Movement at the atlantoaxial joint can also occur less commonly posteriorly, vertically, and laterally. Subaxial subluxation occurs in 5–19% of patients,^{7,8} and subcervical disease can also occur. Predictors of cervical spine disease include severe erosive peripheral joint disease⁸ and use of corticosteroids.⁹ Symptoms include headache, neck pain, and symptoms of spinal cord compression, which always demands urgent investigation. However, according to Neva et al., only 69% of those with radiographic evidence of subluxation reported neck pain.³ Importantly, once objective evidence of neurological impairment has developed, progression appears virtually inevitable and chances of recovery following surgery are reduced.¹⁰

Medical Management of Rheumatoid Arthritis

Essential to the successful management of rheumatoid arthritis is a multidisciplinary approach, involving both early disease-modifying pharmacological treatment to reduce joint deformity and disability, but also pain management and functional restoration strategies.

Pain Management

Despite the advent of disease-modifying antirheumatoid drugs (DMARDs), the majority of rheumatoid arthritis patients continue to experience pain¹¹ and rank pain as one of the most important areas in which they would like to see improvements.¹² Unfortunately, many studies into pain management of rheumatoid arthritis are of varying quality and were carried out in the pre-DMARD era. Multinational recommendations support the use of paracetamol as a first choice analgesic, with consideration of adding a drug of a different class if this is ineffective.¹³ Renal, cardiovascular, and other comorbidities must be taken into consideration, though no studies have directly addressed these groups.¹⁴ Despite a lack of convincing supporting evidence, tricyclic antidepressants or neuromodulators may be a helpful addition in some patients, but muscle relaxants or systemic glucocorticoids are not recommended for pain relief.¹³ Nonpharmacological strategies such as hydrotherapy and orthotics can also reduce pain and maintain function.

Rehabilitation and Functional Restoration/Preservation

Despite modern disease-modifying treatment, many rheumatoid arthritis patients still report reduced function and ability to work.^{15,16} Patients with atlantoaxial involvement have reduced range of motion and neck strength compared to other rheumatoid arthritis patients.¹⁷ No studies have specifically assessed rehabilitation in rheumatoid arthritis patients with spinal involvement. However, general strategies that may be of benefit include resistance and aerobic exercise,^{18,19} hydrotherapy,²⁰ occupational therapy,^{21,22} and splints.^{23,24} Neck exercises should be avoided in patients with unstable atlantoaxial subluxation as it may decrease the width of the spinal canal.²⁵

Evolution of DMARDs

Disease-modifying antirheumatoid drugs are agents that slow disease progression and have shown good efficacy at reducing peripheral joint inflammation. They can be either synthetic, such as methotrexate, or biological agents. It has become recognized that early DMARD treatment²⁶ and tight control of inflammation²⁷ are needed to reduce long-term deformity and disability. Due to a combination of evidence of effect^{28,29} and a relatively acceptable (compared to other DMARDs) safety profile, methotrexate represents

the most commonly used first-line agent. For those unable to tolerate methotrexate, or where it is contraindicated, options include other nonbiological DMARDs such as sulfasalazine or leflunomide. If active inflammation continues despite synthetic DMARD therapy, consideration can be given to a biological agent, most commonly a tumor necrosis factor (TNF) inhibitor, usually in combination with methotrexate.^{30,31} Other second-line agents with effects on skeletal manifestations include the B-cell depleting medication, rituximab³² and the anti-interleukin 6 agent, tocilizumab.³³

The effects of DMARDs on spinal and systemic manifestations have been less well studied and further evidence is needed. While combination DMARD therapy may not show overall benefit over methotrexate alone in peripheral joint inflammation,³⁴ there is limited evidence that it may reduce atlantoaxial subluxation.³⁵ A noncontrolled retrospective cohort study also suggested that biological treatments may reduce the development of new cervical spine lesions, but not pre-existing lesions.³⁶ While a wide variety of disease-modifying and immunosuppressive medications have been tried for systemic manifestations, the evidence is limited and mainly restricted to case reports and small studies.

Imaging

In cases of known rheumatoid arthritis, imaging is required to detect and monitor (1) spinal instability and alignment, and (2) neurological compression and on occasion radiological changes within the spinal cord before clinical manifestations occur. In addition, a detailed knowledge of the individual's bony anatomy may be required to plan the placement of surgical implants.

Dynamic plain radiographs (taken with the head in flexed and extended positions) are used as well as the standard anteroposterior, lateral, and odontoid peg views (Fig. 29.1). These can be used to aid the identification of instability although the definition of instability itself is widely debated. Collins et al. reported that 50% of patients with abnormal cervical spine X-rays were asymptomatic.³⁷ Computed tomography (CT) provides useful assessment of bony anatomy, and software reconstructions of the axial sequences can provide three-dimensional imaging. However, magnetic resonance imaging (MRI) gives the most comprehensive view of soft-tissue and bony spinal involvement in rheumatoid arthritis. Cross-sectional imaging with

Fig. 29.1: Radiographic measurements of OC and C1-2 instability.

both these modalities eliminates overprojection from adjacent structures. Increased signal on MRI T2-weighted sequences can identify changes due to spinal cord compression in addition to detailing the cord contour and identify the pathology (e.g. pannus, C) occupying the perineural space. In common with other spinal pathologies such as standing position and flexion-extension, MRI will probably become more widely used to provide more “real-time” information and allow better correlation with symptoms.

DIAGNOSTIC CHALLENGES

Failing Musculoskeletal System versus Progressive Neurological Deficit

Muscle weakness is a common symptom in rheumatoid arthritis and can have a variety of causes. A key challenge can be differentiating between weakness due to joint inflammation, myopathy, peripheral neuropathy, and spinal cord compression. Clinically, it can be helpful to consider the pattern of distribution of the weakness. Whereas joint pain resulting in muscle disuse would be expected to be local to the affected joint with no increase in tone, spinal cord compression would typically result in a distinct sensory level, with spastic muscle weakness, and possibly bladder and bowel disturbance. Myopathic weakness, due to inflammation or medications, would be expected to be predominantly proximal and symmetrical, whereas peripheral neuropathy would typically be distal, or affect specific peripheral nerves as part of mononeuritis multiplex.

Grading Myelopathy

Grading systems permit a reproducible means of measuring disease progression and the influence of intervention. Grading of neurological deficit in rheumatoid arthritis is complex as spinal cord abnormalities, peripheral nerve compression, and joint arthropathy all lead to symptoms and signs that underlie disability. Functional capacity is most usually graded using the Ranawat scale:³⁸

- No neurological deficit
- Subjective weakness, dysesthesia, and hyper-reflexia
- Objective weakness and long-tract (upper motor neuron) signs; patient is still ambulatory
- As above but patient is no longer ambulatory

Disease-specific Local Challenges

It is important to recognize that rheumatoid arthritis is not simply a disease of joint inflammation, but can have a variety of other local and systemic effects which may be relevant when planning surgery.

Osteopenia/Osteoporosis

Decreased bone mineral density in rheumatoid arthritis is common³⁹ due to a combination of immobility,⁴⁰ inflammation,^{39,41} glucocorticoid treatment,^{39,41} and the female preponderance of rheumatoid arthritis.¹ It can be local, systemic, or periarticular, resulting in increased fracture risk and challenging spinal surgery. Greater disease activity and longer duration of disease appear to be particularly important determinants of bone loss in rheumatoid arthritis,^{39,41} suggesting an important role of inflammation. However, while anti-TNF treatments may halt decreases in bone mineral density,^{42,43} the effects of methotrexate and other nonbiological DMARDs are less clear.⁴⁴ To help identify those at greatest risk, one study demonstrated that a combination of five criteria (age, weight, immobility, inflammation, and ever having used glucocorticoids) had a sensitivity of 82% and specificity of 45% for identifying osteoporosis on dual energy X-ray absorptiometry scanning.⁴⁰

Temporomandibular Joint Dysfunction

Approximately half of rheumatoid arthritis patients have symptoms or signs of temporomandibular (TMJ) joint dysfunction,⁴⁵ such as TMJ pain, clicks or crepitus, and less commonly, restriction of mouth opening. Obstructive

sleep apnea due to rheumatoid arthritis-induced retrognathia has also been reported.^{46,47} If cervical spine surgery is being considered, the effect of coincident TMJ disease must also be taken into consideration as spinal fixation in an inappropriate position may affect an already limited mouth opening. This is potentially important as in one study, half of those with severe cervical spine arthritis on imaging also had a severe TMJ disease.⁴⁸

Esophageal Dysmotility

Investigations into esophageal dysmotility in rheumatoid arthritis are largely confined to small case-control studies and case reports. However, the evidence that is available suggests that approximately one-third or more of rheumatoid arthritis patients may demonstrate dysphagia and more may show asymptomatic esophageal motor abnormalities.⁴⁹⁻⁵¹ Consideration should therefore be given to the effects of this when planning surgery on the cervical spine. Causes may include vasculitis, amyloidosis, cricoarytenoid dysfunction, and xerostomia. There is also a single case report of acute dysphagia secondary to a rheumatoid pannus involving the anterior cervical spine and causing esophageal compression.⁵²

Risk of Deep Vein Thrombosis

Rheumatoid arthritis is associated with an approximately twofold increased risk of deep vein thrombosis (DVT) and pulmonary embolism^{53,54} among both hospitalized patients and outpatients. Surgery and ensuing immobility may increase this further. Although some studies had suggested that anti-TNF medications may increase DVT risk further still,^{55,56} this is not borne out compared to nonbiological DMARDs in a large registry study.⁵⁷

Myocardial Infarction

Rheumatoid arthritis is associated with increased premature mortality,⁵⁸ largely due to an ~50% increased risk of cardiovascular disease.⁵⁹ Myocardial infarction in rheumatoid arthritis patients also appears more likely to go unrecognised⁶⁰ and be recurrent than in the general population.⁶¹ For this reason, risk of cardiovascular disease must be considered in all rheumatoid arthritis patients, especially preoperatively. Potential explanations include systemic inflammation-induced endothelial dysfunction⁶²; similarities exist between the pathological processes underlying rheumatoid arthritis and atherosclerosis⁶³

and an excess of traditional cardiovascular risk factors in rheumatoid arthritis patients. Supporting the role of inflammation in the increased cardiovascular disease risk, patients on methotrexate and those who show a positive response to anti-TNF therapies have a reduction in cardiovascular events.⁶⁴

Immunosuppression

Rheumatoid arthritis patients have an inherent increased risk of certain infections^{65,66} and malignancies such as lymphoma⁶⁷ than the general population. This may be further confounded by the use of anti-TNF therapies,^{66,68} methotrexate and glucocorticoids as treatments,⁶⁹ especially during the first 6 months of anti-TNF treatment. Whether the risk of immunosuppression is such that DMARDs should be stopped preoperatively to reduce postoperative infections is a controversial area. While spinal surgery was not specifically studied, methotrexate does not appear to need to be stopped in patients undergoing elective orthopedic surgery.⁷⁰ The situation for anti-TNF therapies has not been well investigated;⁷¹ however, various national guidelines recommend consideration that they be stopped.

Regional Spinal Disease

Atlantoaxial subluxation (AAS) is defined as a preodontoid interval >3 mm that is not static in dynamic lateral films.⁷² Anterior is the most common direction for this to occur, and lateral subluxation is usually seen in conjunction with rotational deformity.⁷³ The space available for the spinal cord decreases as the preodontoid interval (or anterior atlantodental interval, AADI) increases. One clinical challenge is to predict, if there is a critical preodontoid interval (AADI) at which intervention should occur. Schmitt-Sody et al. have reported no correlation between AADI and neurological symptoms with no significant change to this radiological parameter following surgery.⁷⁴

Evolving instability within the cervical spine can lead to cranial settling (the migration of the odontoid peg into the foramen magnum) occurring in conjunction with AAS. The detrimental effect of this on the autonomic nervous system in addition to the cerebral blood supply necessitates early detection. A number of radiological measurements have been used to assess patients and identify this abnormality. Kwong et al. have suggested that the McRae line is the easiest to measure as cross-sectional imaging is now the normal format for investigation.⁷⁵ However, the decision on timing of surgery is a controversial one without

a clear direction in the literature. Perhaps predictably greater improvement in symptoms postoperatively has been reported in patients with a lower Ranawat grade preoperatively,⁷⁴ leading to the conclusion that cervical stabilization should be performed prophylactically prior to the presence neurological symptoms.

Subaxial subluxation can occur as part of the pathological process with destabilization of the spine due to involvement of intervertebral discs, facet capsule, and interspinous ligaments or secondary to atlantoaxial fusion. Excessive correction of the atlantoaxial angle and the formation of extensive bony union at C1–C2 following such surgery are risk factors for subaxial disease.⁷⁶ A study examining the correlation between myelopathy and MRI findings appears to demonstrate that subaxial subluxation and subsequent stenosis are better tolerated than atlantoaxial stenosis and are less likely to lead to myelopathy.⁷⁷ However, patients with subaxial disease have a poorer improvement in symptoms after surgery compared to those whose indication was atlantoaxial pathology.⁷⁸

Subcervical spine disease in rheumatoid arthritis has received less attention, although the prevalence of this may be higher than traditionally thought.⁷⁹ In addition, asymptomatic pathology below the neck may coexist with cervical disease or be difficult to distinguish from degenerative spondylosis.^{80,81} The primary pathophysiology in the thoracolumbar spine may be intravertebral or inflammatory degeneration of the endplates.⁸² Surgery is not normally required but vertebroplasty for painful bony collapse can be used,⁸³ and florid thoracic facet-joint synovitis resulting in spinal cord compression has been reported, highlighting the need for full cervicothoracic imaging in patients presenting with myelopathy.⁸⁴

Spinal surgery in patients with rheumatoid arthritis is challenging both for local and systemic reasons. Instrumented fusion and neurological decompression are performed prophylactically to prevent the progression of bony instability or occurrence of myelopathy or therapeutically for pain (mechanical neck pain or C2 radiculopathy), deformity leading to functional deficit or to attempt to prevent neurological deterioration when symptoms of myelopathy are already present.

Preoperatively patients need to be assessed by a multidisciplinary team involving surgeons, rheumatologists, anesthesiologists, cardiologists, respiratory physicians, occupational, and physiotherapists. Halo traction prior to surgery can be of benefit. This may allow controlled reduction of deformity in an awake patient and give a better guide to the optimal position in which to place the patient once neurology cannot be so easily assessed under anesthesia.⁸⁵

Anterior (cervical, transoral, or transnasal⁸⁶), lateral, and/or midline posterior approaches to the cervicothoracic spine can be utilized. When a posterior approach is utilized, laminectomies permit decompression of the spinal cord and nerve roots but without stabilization have been reported to lead to a 15–37.5% incidence of instability/kyphosis with subsequent longer-term functional/neurological deterioration.⁸⁷ Multiple techniques are described for stabilization of the occipitocervical (OC) and atlantoaxial segments (Magerl's, Harms) but in common with subaxial spinal surgery, lateral-mass screw/laminar hook and rod constructs are now the most widely used forms of instrumentation.⁸⁸ The aim of all the techniques is to provide early stability to allow a solid fusion to take place and reduce the need for external immobilization. Screw fixation within the bone may be augmented with sublaminar wiring techniques, particularly in view of the higher rate of osteoporosis in patients with rheumatoid arthritis. It is important to consider the overall sagittal balance (an individual's head position in relation to the pelvis) in preoperative planning to aid decision on length of instrumentation and the need to span spinal segment junctions (cervicothoracic/thoracolumbar/pelvic). Grafting techniques with autologous bone, bone substitute, and locally harvested bone (including from the occiput⁸⁹) are all used.

Fusion rates, however, of posterior fusion in patients with rheumatoid arthritis are lower than those with other indications for surgery. Ito et al. with a reported rate of 93% (rheumatoid) and 100% (nonrheumatoid) patients.⁹⁰ As successful union is the major influence on implant failure, it is not surprising that rates of mechanical failure (plate, rod, and screw breakage) are also higher in rheumatoid patients; in a recent study of 142 patients, all such failures except one were in these patients (failure rate 4.2%).⁹¹

Magerl's fusion was the earliest technique described utilizing screws to treat the atlantoaxial segment affected by subluxation. This technique involves bilateral transarticular screws, bone grafting, and traditionally is supplemented by posterior wiring (Figs. 29.2A and B).⁹² This form of instrumentation was a significant advance in terms of achieving solid fusion over the earlier posterior wiring alone described by Gallie among others, which required postoperative halo immobilization. Studies examining the need for sublaminar wires (in addition to transarticular screws) have demonstrated equivalent fusion rates with iliac crest grafting and screws alone.⁹³

The Harms technique of atlantoaxial fusion (C1 lateral mass–C2 pedicle fixation) is an alternative to the Magerl's fusion. A slightly higher fusion rate (97.5% vs 94.6%

Figs. 29.2A and B: Postoperative AP (A) and lateral (B) view following reconstruction.

$p < 0.001$) and lower risk to the vertebral artery (4.1 vs 2% $p = 0.02$) during screw placement are reported on direct comparison of this rod-screw construct to the Magerl's technique.⁹⁴

Preoperative planning with particular reference to CT imaging is essential to ensure the anatomy of the cervical vertebrae, which is often abnormal due to the disease process, as it will permit the surgeon's fusion technique of choice.

There has been a reported trend in the increase of C1–C2 fusions performed in preference to OC fusions for rheumatoid patients with myelopathy and atlantoaxial disease.⁹⁵ Patients have tended to be earlier in the disease process (i.e. less myelopathic) than those treated traditionally with OC fusion but survival rates have improved significantly from 51% (1980–1990) to 81% (2010–2011) with a 9% revision rate of C1–C2 fusions to later OC fusion.⁹⁵ The use of C1–C2 fusion with sparing of the occiput–C1 segment permits the retention of a large amount of anatomical movement and should reduce the risk of subaxial adjacent degeneration. A recent investigation, with a mean follow-up of 9.4 years, has suggested that C1–C2 fusion can be used with a very low risk of degeneration at the OC segment supporting the belief that OC fusion should not be used prophylactically when disease is only radiologically evident at the atlantoaxial (AA) segment.⁹⁶

Posterior decompression and instrumentation may need to be performed in conjunction with anterior decompression by removal of the odontoid peg in cases of basilar invagination from an accumulation of pannus or an abnormally positioned dens. Traditionally, the transoral approach has been used for this but other techniques,

for instance a transnasal, transclival method, have been utilized with success.⁹⁷

Patients with craniocervical or subaxial disease are treated with OC instrumented fusion with “rigid” rod/occipital plate and pedicle/lateral mass screw constructs. An as yet unpublished recent study that analyzes the largest series to date ($n = 100$ OC fusions) has demonstrated significant improvements in neck and myelopathy disability measurements after OC fusion with fusion rates of 70% using radiographic analysis alone; 4% instrumentation failure (metalwork breakage or screw pullout) and a case of improvement from Ranawat 3b to 3a (nonambulatory to ambulatory). This last point is important as traditionally OC fusion was considered to be associated with poor outcome in patients with rheumatoid disease functional status Ranawat.⁷⁴ The significant improvements in medical treatment of rheumatoid arthritis and perioperative care of these patients may mean that the surgical care of such cases with severe disease needs to be reconsidered.⁹⁸

INTRODUCTION

Ankylosing spondylitis (AS) was first described by the neurologists Strumpell, Marie, and Bechterew in the late 19th century. It was therefore called Marie–Strumpell disease, Bechterew’s syndrome, or rheumatoid spondylitis. This disease is predominant in young men and in those who are positive in HLA (human leukocyte antigen)-B27 test. It has an insidious onset of vague low back pain, and as the disease progresses, pain worsens at late night and early morning, and decreases as the day goes by. Moreover, pain markedly decreases or disappears after complete spinal ankylosis. As the disease progresses, low back pain migrates to upper thoracic and cervical regions and the range of movement of spinal column gradually decreases and eventually becomes bony ankylosis of the entire spinal column. Early radiological changes are superior and inferior corner squaring of lumbar vertebral body, pseudowidening, and erosive changes of the sacroiliac joint. Skeletal involvements besides spinal pathology are hip and shoulder joints, and extraskeletal manifestations include iridocyclitis, aortitis, and cardiac conduction abnormalities.

Spinal involvement results in synovitis, followed by bony ankylosis of facet joint, ossification of anterior longitudinal ligament (ALL), interspinous ligament, and ligamentum flavum. The main treatment in the acute inflammatory

phase is pain control and frequent stretching and exercise to delay joint ankylosis as long as possible while avoiding flexed positioning of the torso. In the established phase, the main treatment objective is to control of fatigue pain due to deformity and to correct the poor posture rather than pain.

NONOPERATIVE TREATMENT

Exercise Role

Several trials have displayed the benefits of physiotherapeutic exercise that include increased spinal mobility and the reduction of functional impairment.¹

MRI is beneficial for early diagnosis due to the ability to detect sacroilitis earlier than alternative forms of radiographic imaging.¹ Additionally, MRI can visualize inflammatory changes of sacroiliac joints earlier than other imaging tools.¹

Biologic Agents

Tumor necrosis factor alpha antagonists have demonstrated the ability to act as disease-modifying agents. These drugs target inflammatory pathways utilized by the immune system that underly the origin of AS and consequently provide significant symptomatic relief.

MEDICAL TREATMENT

At present, the only medication known to suppress bone formation and advance of the disease is nonsteroidal anti-inflammatory drugs (NSAIDs). Of the disease-modifying antirheumatic drugs, which were formerly used, only sulfasalazine is effective in peripheral arthritis, while the rest drugs have uncertain effects and are, thus, not recommended. If treatment with two or more NSAIDs is not effective, biologic agents, such as tumor necrosis factor (TNF) blocker are recommended.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs, the first treatment choice, are the only medication known to suppress bone formation. They decrease inflammation by suppressing production of prostaglandin, an inflammatory mediator, by suppressing cyclooxygenase in arachidonic pathway. Thus, constant use of NSAIDs theoretically decreases inflammation and bone formation.^{2,3}

Antirheumatic Drugs

Sulfasalazine, methotrexate, etc. are occasionally used, but have fewer effects on spinal symptoms.

1. *Sulfasalazine*: This resolves into sulfapyridine and 5-aminosalicylic acid by colonic intestinal flora. Sulfapyridine suppresses intestinal flora and 5-aminosalicylic acid suppresses inflammation. Taggart et al.⁴ found that sulfapyridine seems to suppress peripheral arthritis by suppressing intestinal flora.
2. *Methotrexate*: It is reported to be effective in a small proportion of patients. It is a purine antagonist and decreases the function of immune cells by suppressing purine that is used in deoxyribonucleic acid synthesis in cell division and proliferation. In rheumatoid arthritis, there is definite evidence of suppression of bone destruction, but the essential mechanism of this suppression is not clear. However, in AS, it is not recommended because the mechanism of disease progression is different.⁵
3. *Biologic agents*: Tumor necrosis factor blocker is an effective drug among biological agents. Infliximab was followed by etanercept, then adalimumab was produced, and new types are being produced. The indication of this agent is a recommendation by a specialist when there is no response to more than two NSAIDs

for >1 month in ASAS (Assessment of Spondyloarthritis international Society) group and four or more points in BASDAI (Bath Ankylosing Spondylitis Disease Activity Index).^{1,6,7} Reactivation of latent tuberculosis can occur often; thus, prevention and examination for tuberculosis is essential.⁸

These TNF-blocker agents show outstanding effectiveness in patients' pain, range of physical activities, quality and function of life. However, whether it changes the course of disease progression is not certain yet.

4. *Glucocorticoid*: The efficacy of systemic steroids is not yet evaluated in clinical studies. However, patients with AS are not recommended for this because they already have severe loss of bone density.⁶

SURGICAL TREATMENT

The main presenting clinical problems related to the spine in established phase are gross fixed kyphotic deformity, acute spinal fracture, and spondylodiscitis. Andersson lesion (AL) is a destructive vertebral caused by minor trauma that occurs in the late stage of the ankylosing spondylitis.⁹

Deformity

The loss of lumbar lordosis or increased thoracic kyphosis seen in patients with AS can result in severe sagittal deformities. And the patients with AS usually have limited neck motion. These kyphotic deformities may restrict the daily activity. In severe kyphotic deformities, there may be decreased function of gastrointestinal system and poor hygiene. The cause of kyphosis is uncertain but possible causes may be positional to reduce the pain, gravity, and a slight flexed position in daily activity, etc.

Corrective osteotomy could alleviate not only clinical problems, but also social problems including restricted horizontal gaze and self-image.¹⁰⁻¹² Various correction methods had been introduced since 1945 when Smith-Petersen first performed.¹³ However, these methods were less popular because of high risk of complications.

In 1963, Scudese¹⁴ first described a lumbar wedge osteotomy in AS and this procedure had become popular by Thomasen.¹⁵ Now this procedure is called pedicle subtraction osteotomy or egg-shell osteotomy. Most of AS patients can be corrected by this method. In 2013, Kim et al. introduced a modified technique of this method as partial pedicle subtraction osteotomy.¹⁶

In severe kyphotic deformity, vertebral column resection (VCR) can be used. This was first described in 1922 by MacLennan¹⁷ and was performed by the posterior-only approach. This procedure was performed with anterior and posterior approaches by Luque¹⁸ and Bradford.¹⁹ In 2002, Suk et al.²⁰ developed the posterior-only approach for vertebrectomy attempting to reduce operation time and complication.

Surgical Planning

When to Operate?

Due to sagittal imbalance of the spine and osteoporosis, pathological fractures can occur in patients presenting with AS. The formation of pseudoarthrosis and fracture can progressively increase kyphotic deformity commonly resulting in nerve dysfunction. Surgical intervention is the only approach that can relieve chronic back pain while simultaneously correcting kyphotic deformity.²¹

When Lumbar PSO?

Lumbar pedicle subtraction osteotomy (PSO) is recommended for the treatment of large sagittal deformities that measure more than 25° of rigid loss of lordosis.

Additionally, PSO correction should be performed at an angle of approximately 30°, which is performed mainly at the lumbar level. Cases presenting with a substantial sagittal imbalance of >10 to 12 cm with a sharp, angular kyphosis are ideal for this approach.²²

When Cervical PSO?

Currently, the only report of PSO in the cervical spine occurred at C7. Due to the location of the apex of the cervical kyphoscoliosis at C6, the PSO was performed at C6.²³

Whether to do Hip or Spine First?

Initially correcting hip joint deformity and adjusting limited range of motion of the hip can play a critical role in planning the degree of spinal deformity correction in patients with severe AS.²³

Perioperative Consideration

Prior to a spinal osteotomy, a careful neurological examination of the patients is essential, even though neurologic deficit is very rare in AS. The somatosensory-evoked potential, motor-evoked potential (MEP), real-time

electromyography, and a wake-up test should be prepared to monitor any changes in the patient's neurological status at the start of the operation, during the procedure, and after correction of the deformity.

It can be difficult to perform endotracheal intubation in cases, in which neck motion may be limited in a flexed position. Therefore, bronchoscopic or tracheostomic intubation might be necessary. Accordingly, a collaborative approach with an anesthesiologist is important. In case of severe flexion deformity of trunk, hip joint flexion contracture, it is very difficult to get prone position. In these cases, operation table should be flexed to fit the patients and multiple pads should be prepared. Occasionally, there may be situations where a table should undergo flexion or extension to achieve deformity correction. For this reason, an electrical motored table that can undergo flexion or extension should be prepared.

If a patient with severe flexion deformity and rigid ankylosis of the cervical spine is operated upon in the prone position, extreme care is needed to ensure that the head is kept clear of the table and does not take any of the body weight. Otherwise, the neck may be fractured or dislocated when an extension force is applied to the spine. During the procedure, the patient's head supporter might be moved, which can exert direct pressure to the eyeballs and induce an occlusion of the retinal artery, potentially leading to blindness.

Sometimes, acute dilatation of the stomach, paralytic ileus, or, in rare cases, superior mesenteric artery syndrome can occur after spinal osteotomy because an abrupt extension occurs from a flexed position. In these cases, nasogastric or rectal tube insertion may be needed during a certain period of time after surgery.²⁴

Osteotomy

The ideal site to perform osteotomy is at the apex of deformity. However, anatomical characteristics of each region should be considered, and the safest and most effective location should be chosen. We have to consider vertebral artery in cervical, cord, and rib cage in the thoracic region, and root level and long lever arm from the osteotomy site to head the in lumbar region (Figs. 30.1 and 30.2).

Thoraco-osteotomy or Lumbar Osteotomy

1. *Surgical technique of Smith-Petersen osteotomy (SPO):* The level chosen for the osteotomy is determined by the lowest degree of ossification anteriorly and the apex of the deformity. In the prone position, pedicle screws

Figs. 30.1A to D: (A) Global kyphotic deformity of the spine showing (B) “chin-on-pubis” deformity of the patient. The chin-brow vertical angle was fixed at 140° . The activities of daily living were severely restricted. Simple (C) anteroposterior and (D) lateral radiographs revealed complete bony ankylosis in which the bones that included the skull and all vertebrae, and both sacroiliac and hip joints were fused into a single bone. The sagittal plane deformities had kyphosis angles of 40° in the cervical spine, 115° in the thoracic spine, and 15° in the lumbar spine.

are inserted from the upper instrumented vertebra to the lower instrumented vertebra. The initial resection is performed on the spinous process at the level to be resected. Portions of the spinous processes above and below the level should also be removed. In the area to be resected, lamina and facet joints are removed completely using an osteotome or Kerrison rongeur in an oblique shape. A gutter is formed as a V shape from the center bilaterally to the oblique directions on the upward and lateral sides. In particular, on the lateral end, the structure between the upper and lower pedicles should be removed completely to prevent nerve root impingement. Commonly, the width of the gutter should be 10–15 mm. After the formation of the gutter, it is closed posteriorly by manual compression and a push down force with a compression device on both sides or extending the operation table. Special care should be taken to undercut the margin of osteotomized lamina in order to avoid neural compression during closure. The rods are then set and decortication with an autogenous morselized bone graft is applied over the entire levels of the corrected segments. By this technique, average correction can be achieved up to 10° – 15° in each segment. Also in the case of fully ossification of ALL it is very difficult to open the ALL during correction.

2. *Surgical technique of pedicle subtraction osteotomy (PSO):* Pedicle screws are inserted into two or three

segments above and below the pedicles to be resected. After identifying both pedicles to be resected, holes are made through the pedicles into the vertebral body. Curettes are used to increase the size of the pedicle holes. The transverse processes are excised at their bases. Using angled curettes, the cancellous bone in the body is pushed anteriorly into the body to create a cavity in the vertebrae. Laminectomy and facetectomy are performed. The posterior and lateral part of the body is decancellized with angled curettes and both pedicles are enucleated with small osteotome. After thinning the posterior and lateral cortical walls with curettes, the posterior cortex of the vertebral body is pushed down into the body. With firm grasping of the cranial and caudal spinous processes with towel clamps, the operating table is extended, gradually closing the osteotomy. Pedicle screw stabilization is performed after confirming that the exiting nerve roots are free. The spinal cord function is monitored continuously by the MEP. The average correction angle is 25° – 40° in each vertebra by this method.

3. *Surgical technique of VCR:* It can be performed either through a combined anterior and posterior approach or through a posterior-only approach. This chapter describes the procedure through the posterior-only approach.

Like other osteotomy techniques, pedicle screws are placed segmentally, except for the resected segments.

Figs. 30.2A to F: (A) Preoperative and (B) postoperative photographs of the patient during cervical pedicle subtraction osteotomy at C6. A correction angle of 45° was achieved. Prone position (C) before posterior vertebral column resection and (D) intraoperative photographs of posterior vertebral column resection on T11 and T12. (E) A clinical photograph and (F) a whole spine standing lateral radiograph at the last follow-up. Correction angles were 45° , 70° , and 30° in the cervical, thoracic, and lumbar spines, respectively, without neurological complication. Excellent improvement of activities of daily living with horizontal gaze was achieved with 10° of chin-brow vertical angle.

Complete exposure should be done to both transverse processes to allow easier removal of the vertebral bodies. If the segments to be resected are located on the thoracic

spine, costotransversectomies should be performed to exposure the vertebral body. The posterior components (spinous processes, lamina, and facet joints) should be

completely removed to the level of the segments that need to be removed. Both pedicles are then removed using an osteotome. During this procedure, the nerve roots should be saved in lumbar spine. However, in thoracic spine, the nerve roots can be sacrificed because these are intercostal nerves. Osteotomy of the vertebral body is performed on either side of thecal sac. Bone resection should be wedged in sagittal plane and may be asymmetric or symmetric in coronal plane to correct kyphosis and scoliosis components. The bone should be removed completely to ensure that anterior cortical breakage should occur. Before the procedure for the contralateral side, fixation should be performed using a temporary rod. The same procedure should then be performed for the contralateral side. A structural autograft, structural allograft, or metal cage should be used for the reconstruction of bone defect. Using the middle column as a hinge, the anterior part undergoes slight lengthening and the posterior part undergoes shortening to obtain the largest possible amount of correction. It is also important to minimize the changes in the length of the middle column at the cord level. Once a deformity correction is complete, connecting between the pedicle screws and rods is performed. To avoid nonunion or pseudarthrosis, we try to minimize the extent of bony defect by bone-on-bone contact. However, in cases of inevitable bony defect, it is covered with a thin rectangular shape autologous bone graft. Then, abundant morselized bone graft is applied after decortications with a gauge or a burr.

Cervical Osteotomy—Technique

Corrective osteotomy of the cervical spine is one of the most challenging procedures because of catastrophic complications, such as irreversible spinal cord injury and possible brain damage from a vertebral artery injury. This procedure is considered riskier than thoracolumbar osteotomy. Urist²⁵ reported the first case of corrective osteotomy for the cervical spine in 1958, an extension osteotomy similar to the SPO of the lumbar spine. He recommended the C7/T1 junction as the optimum site for corrective osteotomy because (1) the spinal canal is relatively wide, (2) the cervical cord and eighth nerve root have good flexibility in this region, (3) damage to the C8 nerve root is less detrimental to the hand function than damage to the other nerve roots, and (4) the vertebral artery is less likely to kink when the neck is extended. Simmons et al.^{26,27} reported the largest series of clinical outcomes after extension

osteotomies in the seating position with local anesthesia and halo fixation. With the development of modern anesthesia, neuromonitoring, internal fixation, cervical spine osteotomy in the prone position—using strong internal fixation and somatosensory-evoked potential and/or MEP monitoring under general anesthesia—is considered a standard procedure in many reports.²⁸⁻³⁰

Osteotomy technique has advanced continuously as well. Conventional extension osteotomy has the largest number of reports and cases.^{26,28,29,31-34} These articles reported excellent clinical outcomes but a non-negligible rate of complications as a result of the loss of correction and related neurological complications. In 2002, El Saghir and Boehm³⁵ reported that corrective osteotomy consists of posterior osteotomy after an anterior release. Mummaneni et al.³⁶ reported a similar anterior-posterior-anterior 540° procedure to allow for safer correction with structural stability.

Most recently, a closing osteotomy technique on C7 using the pedicle subtraction procedure for the cervical spine was reported by Tokala et al.³⁷ in 2007. Similar to PSO on the thoracolumbar spine, PSO on the cervical spine has the advantages of structural stability and a wider cancellous contact surface for bony union over the extension-type osteotomy.

ACUTE SPINAL FRACTURES IN PATIENTS WITH ANKYLOSING SPONDYLITIS

Several studies have been shown patients with AS to have a fourfold fracture risk compared to general population and the lifetime incidence ranges from 5 to 15%.³⁸⁻⁴¹ Stress shielding, immobility, and increased bony resorption also contribute to osteoporosis as the disease progresses. Ossification of longitudinal ligament, calcification of the annulus fibrosus, and ankylosis of facet joints make a spine rigid, brittle beam with long lever arms reducing the ability to absorb energy from trauma.⁴²⁻⁴⁵ Global kyphosis may induce an impaired balance with gait disturbance and loss of horizontal gaze. So, AS patients have an increased risk of falling.

Hyperextension injury comprises ~75% because pre-existing kyphotic deformity is more susceptible to extension force. Other patterns are flexion, rotation, and compression. Most fractures occur in the subaxial cervical spine and cervicothoracic junction (81.2%), with C5–C6 and C6–C7 as the most common level.⁴¹ Oblique orientation of junctional facet joint and small-sized cervical vertebra carrying

Figs. 30.3A to C: A 44-year-old woman diagnosed with ankylosing spondylitis slipped down while taking a bath. She used to have difficult anterior vision due to kyphotic deformity. She complained of pain in the back after trauma and had tenderness around thoracolumbar junction without any neurologic deficits. (A) Lateral radiographs and (B) 3D-CT show bony ankylosis of the spine with wedge-shaped fracture gap between L1 and L2 and pseudarthrosis at L3 and L4. We performed transpedicular wedge resection osteotomy on T12 and L1 to obtain fracture fixation and simultaneous deformity correction. A cage with massive bone graft was inserted between the gaps for bony union. After 6 months, the patient has improved in anterior vision with improved kyphosis and (C) she was painless as the X-ray shows fracture site united well (3D: Three-dimensional; CT: Computed tomography).

the head weight are the main reasons.^{46,47} Thoracolumbar fractures, mostly happen at the thoracolumbar junction area, are significantly less common than in the cervical region. Neurologic deficit risk ranges from 33 to 50% and is relatively low compared to cervical fractures.^{42,48} Most fractures are also highly unstable.

Fractures in AS have a high risk of neurologic complications. One study reported that about two thirds of patients have a spinal cord injury at initial presentation. This is ~11 times higher than the general population.⁴⁹ About one third of patients had delayed diagnosis caused by the patient or the physician. Pre-existing axial pain indistinguishable from fracture pain and low-energy impact mechanism cause patient delays.^{50,51} Difficult plain X-ray findings at the cervicothoracic junction could be a missed diagnosis by the physician.⁵² So physicians should have special awareness with high index of suspicion to AS patients with ambiguous symptoms even after minor trauma.

Any patient of AS presenting with pain in the neck or back following trauma, however trivial it may be will need evaluation by CT scan, X-ray, & Ct scanMRI pictures pictures

Nonoperative treatment is not suitable for fracture patients because most fracture patterns are unstable with long lever arm and three-column involvement. Although

there may be no neurologic deficit and deformity, secondary neurologic deficit with delayed dislocation happens in ~60% of patients. Infection, skin ulceration, fracture malunion, and pulmonary impairment could all occur with conservative treatment.⁴² Surgical treatment is also indicated in cord compression with neurologic deficit, neural compressive epidural hematoma, and spinal deformity.^{43,53,54} Using axial traction to get realignment, gentle traction with 5–10 pounds is important. Overdistraction may occur well due to instability and paraspinal muscle deconditioning.⁵⁵ Surgical positioning is the most important and critical point. Intraoperative positioning should be adjusted with pre-existing kyphotic deformity using proper support in all regions (Figs. 30.3A to C).

Surgical approach is dependent on fracture locations and patterns. Due to the frequency of cardiopulmonary co-morbidities in AS patients, the likelihood of complication or morbidity increases when using an anterior-posterior approach. For fractures of the lower cervical spine, lateral mass screws up to the C-3 level can be used, and in certain cases, pedicle screws at the C-2 level may be necessary. When reconstruction spans the cervicothoracic junction, thicker rod diameter and materials should be evaluated to ensure stability.⁵⁶

SPINAL PSEUDARTHROSIS

A “bamboo spine” appearance resulting from syndesmophyte formation is typical in advanced AS patients. Although less common, destructive lesions of the intervertebral disc and vertebral body are also found in AS. The pathophysiology, natural history, and even the terminology of this lesion in AS have been controversial.

These lesions were reported in 1937 by Andersson.⁵⁷ Since then, several reports have described these lesions differently. The term “spondylodiscitis,”⁵⁸⁻⁶⁰ which implies inflammatory etiology, was used by some authors. Although the cause of these lesions was initially unclear, other authors described them as “destructive vertebral lesion”⁶¹⁻⁶⁴ or “spinal pseudarthrosis.”^{65,66}

Possible mechanisms for the formation of pseudarthrosis have been suggested. First, since spinal ossification in AS may not be contiguous, the skipped segments that have not completely ossified are exposed to increased stress due to the long ankylosed segments. The mechanical stresses may cause increased wear at the discovertebral junction, followed by fibrous repair. Kim et al. reported that a history of trauma or an inflammatory reaction was not present in all AS patients with pseudarthrosis, although they might be found occasionally.⁶⁷

Although a few AS patients who had spinal pseudarthrosis remained asymptomatic, spinal pseudarthrosis in AS may occur with sagittal plane deformity and may cause severe pain and neurologic symptoms from fibro-osseous tissue proliferation around the lesion.^{65,66} The kyphotic deformity associated with AS results in increased gravitational stress concentration at the pseudarthrosis site between the long lever arms. In 1984, Simmons and Goodwin⁶⁰ described the high incidence of pseudarthrosis in kyphotic patients and attributed it to the severity of deformity. Most authors have reported the thoracolumbar segments as the most frequent site of pseudarthrosis. As the thoracolumbar segments are subjected to the highest stress in the kyphotic spine, the mechanical theory of pseudarthrosis has been supported. The operative findings of spinal pseudarthrosis proliferated osteophytes and fibrotic tissues around pseudarthrosis, which had been ossified and adhered to neural tissues to variable degrees. Sometimes there could be dural defect around pseudarthrosis.

When to Conserve and When to Operate?

It is widely accepted that operative treatment should be highly considered when there is a lack of stability of the spine, or when neurological impairment exists.⁶⁸

Posterior Only Stabilization

Posterior stabilization can provide benefit to patients who present with traumatic fractures that maintain preservation of alignment across the fracture site. Accurate lateral mass plating above and below the fracture is critical for successful fixation and fusion when using the posterior approach.⁶⁹

Posterior and All Posterior Reconstruction

Surgical treatment of pseudarthrosis in AS patients should be focused on stabilization and sagittal realignment. In cases with kyphotic deformity, Smith-Petersen type osteotomy could be considered. After posterior closing of both ends of osteotomy, a bone defect was almost absent or very less, and the amount of the local bone was adequate for posterior fusion. Anterior interbody fusion (AIF) for pseudarthrosis allows for repair of the lesion, including complete curettage and bone grafting. Surgical repair of pseudarthrosis with AIF provided successful fusion and good clinical results. For patients with lumbar hypolordosis, additional PSO was effective in restoration of sagittal balance (Figs. 30.4A to C).

KEY POINTS

- Prior to operation in AS, a thorough understanding of the anatomy of the adjacent structures, such as the neural structure, visceral structure, and spinal column, as well as sufficient surgical technique are essential. In addition, consideration of the myriad of potential complication that might occur is important. Therefore, well-organized teamwork with other departments including the anesthesiology, internal medicine, neurology and rehabilitation is indispensable.
- Nonoperative treatment is not suitable for fracture patients in AS because most fracture patterns are unstable with long lever arm and three-column involvement. Secondary neurologic deficit with delayed dislocation happens in ~60% of patients with conservative treatment. Surgical treatment is also indicated in cord compression with neurologic deficit, neural compressive epidural hematoma, and spinal deformity.
- Surgical repair of pseudarthrosis with AIF provides successful fusion and good clinical results. For patients with lumbar hypolordosis, additional PSO is effective in restoration of sagittal balance.

Figs. 30.4A to C: A 53-year-old man complained pain in the thoracolumbar junction. He was diagnosed with ankylosing spondylitis 7 years ago. Radiologic examination shows global kyphotic deformity and pseudarthrosis between (A) T11 and (B) T12. (C) We performed PSO on L2 and anterior support with bone graft on T11–T12 via left side extrapleural approach after 10th rib removal. PSO, pedicle subtraction osteotomy.

INTRODUCTION

With the advancement of biologics and new bone biomaterials, as well as new data challenging many of the established notions of nonlocal autograft, the subject of bone graft harvesting has become an increasingly controversial topic of discussion. While the use of iliac crest-harvested autograft remains the gold standard, the trend of investigating alternatives has persisted, with a rapidly growing body of literature. New data have emerged in recent years challenging the traditional understanding of nonlocal autograft harvest and associated complications thereof. This chapter presents a review of the techniques and complications of bone graft harvesting, as well as a discussion of the most recent literature on the subject.

CURRENT GRAFT OPTIONS

Autologous Bone Graft

Nonlocal autograft is most frequently harvested from the anterior or posterior iliac crest, although alternative options exist with specific indications.

Iliac Crest

Iliac crest bone graft (ICBG) remains the gold standard because of the unparalleled combination of osteoinductive, osteogenic, and osteoconductive properties,¹⁻⁴ as well as its porosity that helps to promote graft vascularization.

In addition, its ease of harvest from both the anterior and posterior crest, as well as its versatility of use as either a cancellous or cortical graft, allows ICBG to be applied in virtually any fusion surgery. The anterior crest is preferred in cortical applications as the graft may bear much higher axial loads,⁵ while the posterior crest is the preferred source for cancellous graft due to a larger volume of harvestable cancellous bone.⁶

Local

Local autograft obtained from the laminectomy portion of posterior lumbar fusion has been increasingly used in these procedures. The fusion rate with the use of local bone graft in posterior lumbar procedures has been shown to be equivocal to ICBG,⁷⁻⁹ and the volume of local graft harvestable in a single-level fusion is similar to that which can be obtained from the posterior iliac crest.¹⁰

Fibula

Bone graft harvested from the fibula is notable for the large cross-sectional area of cortical bone and the biomechanical stability, and is most commonly indicated in cervical reconstruction following anterior corpectomy. However, because fibular graft lacks many of the osteogenic properties found in cancellous bone, its harvest is frequently deferred in favor of allograft bone or titanium mesh cages in conjunction with cancellous autograft.

Rib

Rib autograft is rarely used, with the exception being when it is harvested as part of the transthoracic approach to the spine, during which time a section of the rib may be removed to improve exposure.

Intramedullary

The reamer-irrigator-aspirator (RIA) system was developed by Synthes in the 1990s in an attempt to reduce intramedullary pressure when reaming for intramedullary nail fixation of the femur and tibia.¹¹ In the mid-2000s, however, experimentation led to the practice of using the system for harvesting intramedullary bone graft, by running the aspirate through a sterile filtration system.^{12,13}

While data are limited, early studies have shown that intramedullary harvest allows surgeons to obtain similar volumes of bone graft as that reported for posterior ICBG, with similar harvest times and a lower rate of major complications.^{14,15} In addition, intramedullary and ICBG share similar transcriptional profiles for genes related to bone formation and repair,¹⁶ as well as for the presence of viable osteoprogenitor cells.^{17,18} Intramedullary graft material was also found to have a greater occurrence of mesenchymal stem cells¹⁶ and colony-forming fibroblasts,¹⁹ which may indicate a more favorable osteogenic and osteoinductive profile. While large-scale clinical trials are needed to determine the efficacy of intramedullary bone grafting for spinal fusion procedures, early case reports in the literature show promise for this application.²⁰

Allogenic Bone Graft

In most series the fusion rates when using allograft, either with or without autograft, are lower than when using autograft alone.²¹⁻²³ However, fresh-frozen cortical allografts have been shown to perform significantly closer to autograft than freeze-dried material, despite the increased immunogenicity and delayed incorporation.²⁴⁻²⁷

SURGICAL TECHNIQUES

Anterior Ilium

There are four techniques of graft procurement from the anterior iliac crest, each with unique advantages and disadvantages.

Tricortical Graft

Tricortical grafts are preferentially obtained from the anterior iliac crest. A direct approach may be used, where

the skin is incised over the crest and the muscular attachments to the inner and outer walls of the ilium are dissected away using periosteal elevators. Additionally, when a retroperitoneal or thoracoabdominal approach to the spine is used, the iliac crest can be reached via subcutaneous dissection over the abdominal wall muscles in order to avoid an additional incision. It is better to opt for an oscillating saw over an osteotome for procuring the graft, as the use of an osteotome has been shown to cause microscopic stress fractures that may weaken the axial strength of the graft.²⁸

Subcrestal Window

The subcrestal window technique allows for the procurement of bicortical graft while leaving the roof of the anterior iliac crest intact. A similar approach is employed as with the tricortical graft, with subperiosteal dissection performed over the preferred region. After appropriate exposure, a straight osteotome or oscillating saw is used to cut the desired section of the bone from laterally to medially, after which the bicortical graft may be removed.

Trapdoor

The trapdoor technique is used when cancellous graft is desired from the anterior approach. Dissection along the medial wall of the ilium is deferred, while a straight osteotome is driven through both walls of the ilium, immediately inferior to the edge of the lateral crest. The periosteum and fascial attachments deep to the medial wall are left intact, and the superficial section of the crest is opened, allowing the medial soft tissues to behave as a hinge. Cancellous bone is obtained via curettage, after which the iliac crest is closed and the lateral fascial layers are reapproximated.

Trephine Method

Trephine curettage can be employed for both the anterior and posterior ilium as a minimally invasive method for obtaining small volumes of bone graft while minimizing postharvest pain. Many variations of this technique have been described in the literature; however, in the majority of cases dissection to the superior edge of the iliac crest is performed, after which a trephine is engaged through the iliac crest between the inner and outer iliac tables. Larger quantities of graft may be harvested by adjusting the angle of insertion of the trephine while remaining parallel to the inner and outer tables of the iliac crest.²⁹⁻³²

Posterior Ilium

Harvesting from the posterior ilium allows for the collection of significantly larger quantities of cancellous autograft, ideal for posterior lumbar arthrodesis. Subcutaneous dissection toward the crest may be performed, if the primary surgical incision is within close proximity. When this is not feasible, a more vertically oriented incision is made 2–3 cm from the midline. This position avoids interrupting the superior cluneal nerves, which course longitudinally, and may pass within 8 cm lateral to the posterior superior iliac spine.³³ A periosteal elevator is used to separate the muscular attachments from the outer table of the ilium, providing clear visualization of the cortex.

To obtain uniform corticocancellous strips, a straight osteotome is employed to make parallel unicortical cuts, perpendicular to the iliac crest along the outer table of the ilium. A curved osteotome may be used to complete the distal and proximal extent of the harvest by connecting the edges of the unicortical cuts in a perpendicular fashion. A straight or curved osteotome is then placed on top of and parallel to the crest, and driven distally in order to unroof the demarcated corticocancellous strips. Gentle tapping of the mallet and careful angulation of the osteotome is essential throughout this harvest in order to avoid violating the inner table of the pelvis. After the corticocancellous strips have been mobilized, the remaining cancellous bone is easily visualized and may be harvested with the use of curettes.

Intramedullary

The technique for intramedullary bone graft harvesting has been well described in the literature,^{13,15,16,34–37} and is very similar to that used for reaming for intramedullary nail placement. The femur is the most frequently harvested bone, and may be approached from either an anterograde or retrograde approach. Patients are positioned supine and fluoroscopy is utilized along with a radiopaque ruler to estimate the diameter of the inner medullary cavity at the isthmus of the femur. Standard minimally invasive entry into the femoral canal is performed until the canal is opened with a cannulated drill and a ball-tipped wire guide is inserted into the femur. At this point, the reamer head size is selected with a diameter 2–3 mm larger than the canal diameter measured at the isthmus, and is gently directed through the femur. Because the RIA has a very sharp cutting head, frequent fluoroscopic checks are necessary to ensure that the cortex is not being reamed

asymmetrically. Reaming is stopped and the sterile filter apparatus attached to the reaming system is emptied when full or when the desired volume of graft material is obtained.

■ COMPLICATIONS

Iliac Crest

Pain

One of the most well-known sequela of ICBG harvest is chronic postoperative donor site pain. While this issue is heavily discussed throughout the literature, there is currently a lack of level-one evidence to adequately quantify it.^{38,39} The traditional understanding of this complication held that chronic pain was extremely common;⁴⁰ however, more recent evidence has shown that this view may be an overestimate.^{41–43}

While the underlying reason for chronic donor site pain of the iliac crest is poorly understood, several options exist for decreasing the likelihood of this adverse event. In some studies, a direct infusion of local anesthetic into the donor site for up to 48 hours after the procedure significantly reduced postoperative pain, even years out from surgery.^{44,45} However, these findings are not without contestation, as other studies have failed to show long-term differences in donor site pain with this intervention.⁴⁶ Further research is necessary to evaluate the true benefit of local anesthetic infusion. The infusion process itself appears to be very well-tolerated, with no reports of long-term complications secondary to its use.

Additional measures may be taken to decrease perioperative and postoperative pain, including a plane block of the L1 dermatome, where local anesthetic is infiltrated into the plane between the transversus abdominis aponeurosis and the transversalis fascia.⁴⁷ For tricortical grafts, reconstruction of the iliac crest defect with either additional segments of local tricortical bone, or with ceramic composite biomaterials, has been shown to be highly effective at decreasing long-term donor site pain.^{48,49}

Arterial Injury

The most common bleeding complication in ICBG harvest is caused by violation of the superior gluteal artery. This artery originates as the largest branch of the internal iliac artery and exits the greater sciatic foramen, traveling in close proximity to the edge of the sciatic notch before extending caudally to supply the gluteal muscles. During

posterior harvest of corticocancellous strips, driving an osteotome too forcefully may cause it to enter the sciatic notch, lacerating the superior gluteal artery and resulting in a brisk bleed.

Repair of the superior gluteal artery can be extremely challenging due to poor visualization of the injury. As the sciatic notch is not easily accessible from an incision made at the posterior iliac crest, it may be challenging to achieve adequate visualization while attempting to repair the defect. Additionally, when a complete transection of the artery occurs, the proximal segment may retract deep to the sciatic notch, requiring a more aggressive dissection. In such a situation, dissection of the superior portion of the sciatic notch is an appropriate maneuver in order to obtain adequate visualization of the artery. The artery should be clearly visualized before clamping or ligation is attempted, due to its close proximity to the ureter and the superior gluteal nerve.

This complication emphasizes the importance of maintaining control of the osteotome at all times, and using gentle taps of the mallet when making parallel cuts into the outer table.

During anterior harvest, aggressive subperiosteal dissection of the inner table may violate the arterial plexus supplying the iliacus muscle. However, due to its easy accessibility and highly anastomotic nature, this arterial injury is typically easier to manage and results in significantly lower patient morbidity than a superior gluteal artery injury.

Nerve Injury

The superior gluteal nerve courses along the gluteal artery, and should be avoided in a similar fashion during posterior harvest. Injury to the gluteal nerve can denervate the tensor fasciae latae, gluteus minimus, and gluteus medius, the latter of which results in the classic Trendelenburg gait.

The superior cluneal nerves, which supply much of the sensory innervation to the buttock, traverse the posterior iliac crest within 8 cm lateral of the posterior superior iliac spine, and may be injured when the posterior incision is continued to this lateral location.

While arterial injury is less common during harvesting of the anterior crest, nerve injury is proportionately more common, often related to aggressive retraction of inner table muscles during the initial dissection, although this is infrequently reported.⁵⁰ The ilioinguinal and iliohypogastric nerves are rarely injured in isolation, and both originate from the lumbar plexus and course laterally in close proximity to the psoas and quadratus lumborum muscles

before perforating the transversus abdominis near the anterior portion of the iliac crest. Injury to these nerves can manifest as a neuralgia consisting of lancinating pain and hyperesthesia or hypoesthesia of the skin along the inguinal ligament and extending from the surgical incision laterally into the inguinal and suprapubic regions.

The femoral nerve and lateral femoral cutaneous nerve (LFCN) also pose a risk for injury during anterior crest harvest, as they travel along the iliacus muscle before exiting the pelvis by coursing deep to the inguinal ligament. Excessive retraction of the inner table components or penetration of the iliacus muscle by an osteotome may cause injury to either of these nerves. Additionally, the course of the LFCN can vary in 10% of individuals in which it exits the pelvis by traversing the iliac crest, rather than diving medially and deep under the inguinal ligament (Fig. 31.1). For this reason, the anterior crest should never be harvested within 2 cm of the anterior superior iliac spine (ASIS).

Other Complications

Stress and avulsion fractures of the ilium are most frequently associated with full thickness grafts from the anterior crest, although there is still a concern for fracture complications in partial thickness grafts, especially in at-risk patient populations, such as those with severe osteoporosis.⁵¹ Avulsion fractures occur most often when tricortical graft is harvested in close proximity to the ASIS, after which the muscular attachments may cause this bony prominence to avulse.⁵²⁻⁵⁴ This, in addition to the previously discussed anatomic variant of the LFCN, further supports the impetus to give a wide berth to the ASIS when harvesting tricortical graft from the anterior crest.

During the harvest of posterior corticocancellous strips, the posterior ligamentous complex supporting the sacroiliac joint may be compromised, resulting in sacroiliac instability that frequently manifests as complex lower back pain that may radiate into the groin, buttocks, and leg. When performing posterior corticocancellous harvest, standing on the opposite operative side of the table from the harvest site directs the osteotome away from the sacroiliac ligamentous complex and decreases the chance of injury to this anatomic structure.

While the iliacus and the abdominal wall muscles serve to protect the peritoneum from violation (and subsequent herniation of abdominal viscera), herniation following iliac crest bone harvest is a potential complication. While the true incidence is unknown, it has been reported in the literature to range from 5% to 9%.^{55,56} Bowel is the most

Fig. 31.1: Variant course of the lateral femoral cutaneous nerve (LFCN) which can place it at risk during anterior iliac crest bone graft harvest. (IL: Inguinal ligament; IM: Iliacus muscle; TFL: Tensor fascia lata; Sa: Sartorius; PMa: Psoas major; PMi: Psoas minor).

commonly affected viscera; however, involvement with other organs has been reported.⁵⁷ Risk factors for herniation include larger tricortical graft harvest and more aggressive dissection and retraction of the inner table components. Repair of these defects is often uncomplicated, although the use of mesh implants may be necessary to close the defect.

The ilium is notable for its rich intracortical blood supply, which is thought to increase the risk of hematoma formation after iliac crest harvesting. Standard preventative measures, such as the application of bone wax or coagulative gel foam, as well as vacuum-assisted wound drainage, decrease the risk of hematoma and are recommended in all cases of bone graft harvest.

Intramedullary

Many of the potential complications of intramedullary bone graft harvesting are similar to that reported for intramedullary nail placement. A case of a femoral neck stress riser has been reported as occurring secondary to an aggressive, large-diameter entry through the piriformis fossa;¹⁴ however, the other current studies on this technique reported no other major complications necessitating return to the operating room.⁵⁸⁻⁶¹ There have been reported cases of

thinning of the anterior cortex due to eccentric reaming with the cutting head, and even perforation through the anterior cortex.⁵⁸ However, these were treated nonoperatively with temporary partial weight bearing restriction, and did not necessitate a return to the operating room. This complication may be avoided by frequent fluoroscopic checks during reaming, paying especially close attention to the lateral view in order to evaluate the anterior cortex. More data with longer term follow-up are needed to determine the true incidence of eccentric reaming into the anterior cortex, and if there is associated morbidity, such as a predisposition for femoral shaft fractures.

KEY POINTS

- Graft harvested from the iliac crest remains the gold standard for autogenic bone graft, and demonstrates superior osteogenic, osteoinductive, and osteoconductive properties to allograft.
- Intramedullary bone marrow harvest with the femoral shaft reamer-irrigator-aspirator represents a potential new source of cancellous bone graft while avoiding many of the complications frequently associated with iliac crest bone graft.

- During anterior iliac crest harvest, the 2 cm of crest proximal to the anterior superior iliac spine should be spared in order to avoid injury to the lateral femoral cutaneous nerve, as well as to decrease the risk of ASIS avulsion fracture.
- Care should be taken to maintain control of the osteotome during iliac crest harvest, as violating the sciatic notch or the inner and outer tables of the pelvis can result in disastrous neurovascular compromise.
- The risk of chronic donor site pain from the iliac crest may be decreased by the use of local anesthetic infusions, transversalis fascia plane block, and crest reconstruction.

This level I study compared the use of local bone grafting to iliac crest bone graft, and showed that local bone graft for single level instrumented posterolateral fusion leads to an identical fusion rate as ICBG, while decreasing surgical time and complications. It should be noted that the only complications that were significantly increased with iliac crest harvest consisted of donor site pain and surrounding area sensory loss. No complications occurring in either group necessitated a return to the operating room.

- Conway JD. Autograft and nonunions: morbidity with intramedullary bone graft versus iliac crest bone graft. *Orthop Clin North Am*. 2010;41(1):75-84.

This study directly compares the volume and quality of graft obtained from both the iliac crest and intramedullary cavity. It also investigates the technique of harvesting from the intramedullary cavity versus the iliac crest,

comparing the harvest time, blood loss, and postsoperative considerations, such as donor site pain and functional impairment.

- Sagi HC, Young ML, Gerstenfeld L. Qualitative and quantitative differences between bone graft obtained from the medullary canal (with a Reamer/Irrigator/Aspirator) and the iliac crest of the same patient. *J Bone Joint Surg Am* 2012;94(23):2128-35.

This study directly compares the genetic and histologic profiles of graft from intramedullary versus iliac bone in ten consecutive patients. It showed that viable osteocytes and their progenitor cells exist in the reaming debris, and that it also displayed upregulation of genes related to bone repair and formation.

- Delawi D, Dhert WJ, Castelein RM. The incidence of donor site pain after bone graft harvesting from the posterior iliac crest may be overestimated: a study on spine fracture patients. *Spine (Phila Pa 1976)*. 2007;32(17):1865-8.

This study shows that patients with spinal fusion occurring at higher vertebral levels were much less likely to report chronic donor site pain. Because lower back pain may be confused for donor site pain, it is possible that patients fail to differentiate the two when reporting chronic donor site pain in other studies.

- Singh K, Phillips FM, Kuo E. A prospective, randomized, double-blind study of the efficacy of postoperative continuous local anesthetic infusion at the iliac crest bone graft site after posterior spinal arthrodesis: a minimum of 4-year follow-up. *Spine (Phila Pa 1976)*. 2007;32(25):2790-6.

This study demonstrated that a continuous 48 hour infusion of 0.5% marcaine into the iliac crest donor site through a catheter-infusion system had a significant effect of reducing perioperative and chronic donor site pain through a follow-up of 4 years. There were no long term complications associated with the infusion system, which was tolerated well by patients.

INTRODUCTION

It is estimated that, globally, more than 500,000 bone grafting procedures related to spine fusion are performed annually.¹ Autologous bone graft is often limited in its availability while its harvesting may be associated with significant donor morbidity. Such reality has stimulated a proliferation of research and corporate interest in identifying and characterizing candidate materials for what is considered an almost limitless market in bone graft replacement.

Today, multiple commercially available bone graft extenders (BGEs) and osteobiologics have been developed with the goal of decreasing surgical morbidity while matching or improving surgical fusion rate. Such enthusiasm, however, must be tempered by objective scientific evaluation and independent clinical testing. Currently, bone graft substitutes, depending on their composition and preclinical testing are subjected to varying degrees of regulatory scrutiny. These inconsistencies make direct comparison of materials difficult and so their true effectiveness in patients is often poorly understood prior to their use by spinal surgeons.

In order to choose appropriate bone graft substitute for our patients and ourselves, it is imperative that we as clinicians have an adequate knowledge of the following issues:

1. The biology of spinal fusion.
2. The characteristics of bone graft material options.
3. Currently available bone graft substitutes.
4. The current best evidence for the use of bone graft alternatives in clinical practice

In this chapter, we will explore these issues in detail, in order to gain a better insight into this myriad group of bone graft alternatives.

BIOLOGY OF SPINAL FUSION

Essentials of Bone Formation

A working knowledge of the basic biology of spinal fusion is essential to a better understanding of the attributes and limitations of bone graft alternatives in a clinical context. The physiological process of spinal fusion has many similarities to that of acute fracture healing,²⁻⁴ occurring through a combination of both intramembranous and endochondral ossification. The essential difference between the

Box 32.1: Intramembranous bone formation.

Step 1: An ossification center develops within the connective tissue, whereby local and systemic mesenchymal stem cells cluster together. These develop into osteoblasts, eventually secreting bone matrix, while some later become trapped within that matrix and become osteocytes.

Step 2: Angiogenesis and vasculogenesis result in blood vessel ingrowth of the matrix, delivering the essential oxygen and nutrients for bone formation. When mature, these blood vessels will become trapped within the developing bone.

Step 3: The immature, or spongy, bone is established.

Step 4: Immature bone remodels under the orchestration of the osteoclast, eventually becoming mature or compact bone.

processes is the relative contribution of a “cartilage intermediary” to the formation of bone, a phase characteristic of endochondral bone formation. While both of these processes are involved in skeletogenesis, long bone growth, bone remodeling, fracture healing and spinal fusion, the essential elements are the same for all physiological and pathological processes of the skeleton.⁵⁻⁷

Intramembranous Ossification

There are *four* key steps in the process of *intramembranous ossification* (Box 32.1).

Endochondral Ossification

There are *five* key steps in the process of *endochondral ossification* (Box 32.2).

BONE GRAFT INCORPORATION

The biology of bone graft incorporation involves many factors.⁴ To look at these factors, we will need to examine several types of grafts. Fresh autograft is the transplantation of living bone that can survive and add to the bone volume and eventually the bone strength. When fresh autograft is added to a recipient site, the incorporation of the graft relates to the recipient site cells as well as to the remaining viable cells within the graft itself. The cellular response seems to be different when using a cancellous graft as opposed to using a cortical one. Cancellous autografts as well as fresh cortical autografts begin their incorporation in much the same way.^{8,9}

Blood clot and hematoma provide the initial environment for the new graft. An inflammatory response then prevails and vascular granulation tissue invades the area.

Box 32.2: Endochondral bone formation.

Step 1: A cartilaginous focus develops in the soft tissues, where precursor cells are driven by ambient oxygen tension and biomechanical load to differentiate into chondrocytes. These cartilage cells subsequently differentiate into osteoblasts, secreting a bony collar.

Step 2: The primary ossification center is established and the cartilage within the central portion undergoes direct ossification.

Step 3: Angiogenesis and vasculogenesis result in vascular invasion of the internal cavities of the primary ossification center, with chondrocytes undergoing orchestrated apoptosis while fibroblasts differentiating into osteoblasts. These osteoblasts secrete an immature spongy bone matrix.

Step 4: During the process of skeletogenesis, a secondary ossification center develops in the epiphysis of long bones.

Step 5: The primary ossification center matures and remodels, forming compact bone with some marrow cavity. In long bones, some hyaline cartilage remains to form the articular and epiphyseal cartilages.

By the end of the second week, the response is that of a fibrous granulation tissue, and cellular death occurs within the graft, which has not yet been reached by the vascular response. At this point, the differences of graft incorporation between cortical and cancellous grafts become evident.

In cancellous autografts, the vascular response is much greater than in cortical grafts. The entire cancellous bed may be completely revascularized within approximately 1–2 weeks. The cell population of this environment comprises predominantly osteoblasts. It is not known if these cells are produced from the recipient site or if they are the descendants of cells transplanted with the graft itself. In any case, these cells line the scaffold presented by the trabeculae of the graft and deposit a seam of osteoid that surrounds and entraps the original dead bone. This entrapped dead bone is eventually resorbed by osteoclasts. Radiographically, the cancellous bone first becomes more dense as the new bone forms on the old trabeculae and then becomes less dense as the osteoclastic remodeling takes place. It would appear that the cancellous graft is completely remodeled and replaced by new bone.^{10,11}

In the cortical autograft, the main differences revolve around the amount of revascularization and the completeness of the remodeling. The cortical bone may not be revascularized as quickly as the cancellous graft. Revascularization takes about 2 months and is caused by the structure of the cortical graft, which does not allow as large

a contact area for vascular penetration between the graft and the host. Revascularization is accomplished through the old haversian and Volkmann canals. Following the revascularity of the periphery of the graft, the interior follows suit quickly. Interior revascularization of a cortical bone graft will start the process of creeping substitution, which first resorbs bone stock before replacement with new viable bone stock. The resorptive phase is seen to be increased over normal levels at 2 weeks, steadily increasing for the next 4 weeks, and then diminishing toward normal by 1 year. The histologic evaluation of this data showed that the resorption process progressed so that the peripheral haversian systems and their adjacent interstitial lamellae were remodeled first and then the interior haversian systems were remodeled without their corresponding interstitial lamellae, thereby leaving areas of dead cortical bone mixed in with the newly remodeled bone. The overall results showed that the bone at the ends of the graft was more completely remodeled than the bone in the center of the graft. The completeness and rate of repair seemed to be related to the remodeling activity, with greater repair associated with more active remodeling. The relationship of this remodeling rate to weight-bearing stresses is unclear.¹¹⁻¹³

The incorporation of cortical allografts differs slightly from that of cortical autografts. In general, the revascularization is much slower and the bone formation is less extensive. Resorption may play a much larger part in the graft incorporation. The temporal sequence of the cortical bone allograft shows an inflammatory response for several weeks. The major cell type at this time is the lymphocyte. The inflammatory response lasts for another month or two, during which time a fibrous *encapsulation* of the allograft takes place. Gradually, the graft may be incorporated into the host tissue. The time period associated with the incorporation of the allograft is one indication of the acceptance or rejection of the graft. Callus formation is a good sign but may not be present to any great extent if rigid internal fixation is used.

■ THREE BIOLOGICAL PHASES OF SPINAL FUSION

Boden, using a rabbit model, was the first to describe in detail the three distinct phases (*the inflammatory phase*, *the reparative phase* and *the remodeling phase*) of the spinal fusion process.^{14,15}

Inflammatory Phase

The *inflammatory phase*, which lasts up to 14–28 days in humans, begins with surgical exposure and bone decortication, leading to hematoma formation and a local accumulation of myriad cytokines including tumor necrosis factor α , basic fibroblast growth factor, vascular endothelial growth factor (VEGF), placental like growth factor and bone morphogenetic proteins (BMPs). Rapid and profuse vascular ingrowth characterizes this inflammatory phase. Intramembranous bone formation occurs immediately adjacent to the site of decortication and is known as the *outer zone* of fusion. Endochondral bone formation predominates between these sites, e.g. *intertransverse* area and is known as the *central zone*.

Reparative Phase

The reparative phase is characterized by further vascularization of the fusion bed, and an orchestrated resorption of necrotic tissue. The pluripotent mesenchymal cells that have migrated from the local soft tissues and via the neovascularization then differentiate into chondroblasts and osteoblasts. The earliest evidence of fusion is seen with ossification of the preliminary cartilaginous tissue into immature spongy bone. Fifty percent of fusion is thought to have occurred by the conclusion of this reparative phase, approximately 42–84 days following decortication.

Remodeling Phase

The *remodeling phase* is characterized by the transformation of immature woven bone into mature lamellar bone with cortical and cancellous components. This has largely occurred by 180 days postdecortication, although fusion mass remodeling continues to occur for life. The anatomical and physiological characteristics of this fusion mass continue to evolve, with the exact nature at any time being determined by the ambient biomechanical and biological environment.

■ CHARACTERISTICS OF BONE GRAFT MATERIAL OPTIONS

When considering the appropriate bone graft substitute, graft extender or osteobiologic for a particular clinical scenario, we must examine the available options cognizant of the biological and structural characteristics shown in Box 32.3.

Box 32.3: Characteristics of bone graft materials.

Osteogenesis
 Osteoinduction
 Osteoconduction
 Osteopromotion
 Structural integrity
 Osteointegrative ability/bioactivity

Osteogenesis

Osteogenic grafts contain a cellular population, with the necessary synthetic machinery, osteoblasts, and/or progenitor cells, which are capable of surviving the transplantation process and can thus independently produce new bone in the transplanted site. Autologous bone graft is the only truly osteogenic graft alternative. Iliac crest (IC) harvested autograft has more osteogenic potential than local bone graft (LBG) from laminectomy/facetectomy.

Osteoinduction

Osteoinductive graft materials contain a profile of cytokines and growth proteins that are necessary to induce the differentiation of progenitor cells into bone-producing cells (osteoblasts). This is a complex process involving the mediation of multiple signaling factors including the transforming growth factor β (TGF- β) superfamily of BMPs. Through this process, a true osteoinductive agent can stimulate bone production anywhere in the body, including nonbony locations. A material is defined as osteoinductive if it is shown to induce ectopic bone formation in athymic nude mice. However, we must be very careful not to equate this property with inherent osteoinductive ability in a clinical setting. Many calcium phosphate bone substitutes have been marketed as osteoinductive on the basis of this model. However, the “osteoinductive” properties of these materials are actually related to their architectural features of geometry, topography, and porosity, which allow attachment of circulating and locally produced BMPs. This concentration of BMPs over time will induce bone formation independent of the calcium phosphate bone graft substitute. Hence, in reality we are observing delayed osteoinduction by BMPs naturally occurring in the body.

Osteoconduction

Osteoconductive grafts provide a bioactive three-dimensional matrix structure, similar to cancellous bone, which

allows for and stimulates bony ingrowth and ongrowth. This matrix supports and facilitates fibrovascular ingrowth, hosts progenitor cell migration into the scaffold, osteoblast attachment and eventual manufacture of new bone. This passive ability depends on direct contact with exposed bony surfaces. Allograft materials and demineralized bone matrix (DBM) are primarily osteoconductive. Demineralized bone matrices may also have weak, inconsistent osteoinductive capacity.

Osteopromotion

Osteopromotive agents enhance de novo bone healing that is already taking place, while these agents may not have any inherent osteogenic, osteoinductive or osteoconductive capabilities. Osteopromotive agents include platelet-derived growth factor (PDGF), TGF β -1, insulin-like growth factor 1 and VEGF, all of which have been shown to have osteopromotive potential in preclinical studies. Platelet-rich plasma (PRP), which contains a concentration of these agents, can be easily derived from whole blood samples using any of a number of commercially available isolation systems.

Structural Integrity

In some clinical situations, e.g. interbody grafting after discectomy or vertebrectomy, a graft material with immediate inherent structural integrity may be required. The clinically relevant material properties of this graft material will include compressive strength, and resistance to torsion and shear. If this structural graft material must be fixed in place, e.g. with a threaded screw, then it should not be *brittle*. A material is brittle, if when subjected to stress, it breaks without significant deformation (strain). Brittle materials absorb relatively little energy prior to fracture, even those of high strength. The processing of many structural allografts renders them brittle.

Osteointegrative Ability/Bioactivity

This is the capability of the graft material to integrate and bond to the host bone through an interaction between the biomaterial and the surrounding tissue. In bone graft substitutes, bioactivity describes the influence of a material on bone formation. By changing surface properties of the graft material, e.g. calcium phosphate ceramics, bone integration and bonding can be influenced. From a cellular

perspective, bioactivity reflects the attachment and differentiation of local native osteogenic cells on the surface of the graft material.

CURRENTLY AVAILABLE BONE GRAFT MATERIALS

To address donor site morbidity, volume availability, potential immunogenicity, and disease transmission, a variety of bone graft substitutes have been developed. No perfect substitute yet exists that embodies all the ideal qualities of autograft (osteogenic, osteoconductive, osteoinductive, structural integrity, bioactivity). Except for BMPs, which are discussed in another chapter in this book, these products do not routinely have osteogenic or osteoinductive capabilities unless mixed with autograft or bone marrow aspirate (BMA). Most of these agents have osteoconductive capabilities, creating a matrix for host cells to regenerate bone. They can also be osteointegrated, reflecting their bioactivity. Bioabsorbability and strength profile should be similar to cortical or cancellous bone, but this remains variable among the different products. Cost is also highly varied. The following is a list of the current most commonly utilized bone graft material types. This list is not designed to be exhaustive of all available products, but rather classifies the products into materially distinct types.

1. *Autologous graft*: structural or nonstructural, local or iliac crest harvested, vascularized or non, BMA
2. *Allograft*: structural or nonstructural
3. DBM
4. Minerals
 - a. Hydroxyapatite (HA)
 - b. Coralline HA
 - c. Ceramics
 - d. Composites
5. Cements
6. Calcium sulfate
7. Bioactive glass (BAG)
8. Osteopromotive agents/autogenous growth factors
9. Cell-based therapies

Requirements for an ideal bone graft substitute are as listed in Box 32.4.

A summary of the advantages and disadvantages of the various graft materials is given in Table 32.1. Techniques and complications of bone graft harvesting, vascularized grafts and BMPs will not be examined in detail in this chapter, as they are the focus of other chapters in this textbook.

AUTOLOGOUS GRAFT

Iliac Crest Bone Graft and Local Bone

The gold standard substance that provides all of the necessary factors for bone formation (osteogenic, osteoconductive, osteoinductive, structural integrity, bioactivity) is autogenous bone (AB) graft. In 1911, Hibbs¹⁶ described the use of LBG in the first spinal arthrodesis performed in the setting of tuberculosis of the spine. Autograft is the preferred bone graft material because of its availability, inherent fusion-developing properties, low cost compared with commercially available grafting substitutes, and the absence of concerns regarding possible disease transmission or tissue incompatibility. The iliac crest, with its potential source of cortical and cancellous bone graft, is the current go to site for *distant site autograft*. These grafts are the benchmark to which allograft and substitutes are compared for in vivo performance.¹⁷⁻²¹

Unfortunately, morbidity associated with its use is also well reported. Donor site morbidity can be attributed to the harvesting procedure of the iliac crest bone graft (ICBG). This procedure is associated with longer operative times, increased estimated blood loss, and a longer hospital stay. Pain is the most common complication, but hematomas, paresthesias, and wound complications can also occur. Some authors have reported chronic pain at the graft site in up to 60% of patients.^{22,23}

In the very cases where large amounts of high-quality cancellous bone graft material is required, e.g. revision long thoracolumbar fusion for deformity in the elderly, there is often less ICBG available for harvest, and the quality of this bone (osteogenic, osteoconductive, osteoinductive,

Table 32.1: Advantages and disadvantages of most common bone grafting options.

<i>Graft material</i>	<i>Advantages</i>	<i>Disadvantages</i>
<i>Autograft</i>		
Iliac crest	Gold standard Large availability, low cost Osteoconductive Osteoinductive Osteogenic	Donor site morbidity Increased blood loss Increased operative time
Local bone	Low cost, minimal morbidity Osteoconductive Osteoinductive Osteogenic	Limited availability Biologically inferior to iliac crest bone graft
<i>Allograft</i>		
Fresh frozen	Large availability, low cost Osteoconductive	Disease transmission Inflammation No osteoinductive or osteogenic capacity
Freeze-dried	Large availability, low cost Osteoconductive	No osteoinductive or osteogenic capacity
Demineralized Bone matrix	Large availability, low cost Osteoconductive	No osteogenic capacity Inconsistent limited osteoinductive capacity
Ceramics	Large availability Immediate structural integrity No immunogenicity	No organic matrix No osteoinductive or osteogenic capacity
β-Tricalcium phosphate	Three-dimensional structure of bone Porous	Brittle Limited compressive strength
Coralline HA	Immediate structural integrity	Slow in vivo resorption
Silicate-substituted calcium phosphate	Immediate structural integrity	Costly No osteoinductive or osteogenic capacity
Calcium sulfate	Quick in vivo resorption Biocompatibility	Quick in vivo resorption Wound drainage
Autologous growth factors	Osteoinductive	Cost Questionable safety/dosing Variable efficacy
Bone marrow aspirate/MSCs	Osteoinductive	Osteoinductive only Needs carrier Questionable efficacy

(HA: Hydroxyapatite; MSCs: Mesenchymal stromal cells).

bioactivity) is poor. These concerns have led to the increasing body of research focused toward developing an ideal bone graft substitute.

Other more recent studies question whether iliac crest donor site pain may be overestimated. Delawi et al.²⁴ found that the incidence of donor site pain was <15% in patients with a more proximal level of fusion compared to 40% in those with a lower level of fusion, suggesting that donor site pain may be related to the lumbar procedure itself and not so much the donor site. Another recent study of 112 patients treated with posterolateral fusion (PLF) with

or without bone graft reported that the incidence of tenderness over either posterior iliac crest was up to 50% in patients who did not undergo crest harvesting. The incidence of concordant pain from the crest where the graft was harvested was only 19%. These studies, therefore, question the assertion that bone graft harvesting is indeed a significantly morbid procedure.²⁵

While autograft is considered the “gold standard” for spinal fusion, it is interesting that it has never been directly compared with no bone graft material, in the clinical setting. Similarly, published fusion rates with autograft

vary with marked differences reported based on fusion location, graft harvest location, surgical technique, use of instrumentation, volume of graft used, preparation of fusion base, and the method used to assess whether bony fusion has been achieved.²⁶⁻²⁸

Transplanted cancellous bone graft may have few osteoblasts, but it does contain precursors that maintain their osteogenic potential and, therefore, their ability to form new bone. The local graft environment also affords an enriched osteoinductive environment and one that is osteoconductive, but has less initial structural strength. Structural or cortical grafts, however, can assist in maintaining structural support while providing osteoconduction and some osteoinduction. Cortical graft, as typically utilized in the intervertebral space or following vertebrectomy, provides strong structural support within the first 6 weeks after transfer, but they are prone to fracture (brittle) and the processes of osteointegration, resorption and remodeling take many months, to years.

Posterior spinal arthrodesis, typically when combined with neural decompression, can provide a large amount of *local autograft bone*, harvested from the laminectomy and facetectomies. Anterior vertebrectomy, usually in the setting of trauma or deformity, also provides a large amount of local autograft bone. Local bone graft harvesting does not require separate exposure and avoids many of the complications associated with iliac crest graft harvesting. Disadvantages of local bone include its relatively limited quantity, particularly in the setting of revision surgery with prior laminectomy, and its greater composition of cortical bone compared to cancellous bone.

While intuitively there is concern regarding poor fusion rates associated with its use, several studies have reported fusion rates that are comparable to those achieved by ICBG, particularly for single-level fusions. In a retrospective comparative study of 76 patients treated with instrumented PLF, Sengupta et al.²⁹ report overall fusion rates of 75% with ICBG and 65% with local bone. However, when only multilevel fusions were included in the analysis, the difference was significantly greater with fusion rates of 66% for ICBG and only 20% for LBG. Despite decreased rates of fusion, no significant difference in overall clinical outcome is noted between these two groups, absent those patients ultimately requiring a revision for pseudarthrosis.

Ohtori et al.³⁰ prospectively examined single-level instrumented PLF at L4-L5 with a LBG versus an ICBG for degenerative spondylolisthesis. Eighty-two patients were randomized into a local autograft group ($n = 42$) and

an ICBG group ($n = 40$). Rate and time to fusion were equivalent (90% fusion at 8.5 months in the LBG group, and 85% fusion at 7.7 months in the ICBG group). Schizas and coworkers prospectively reviewed 59 patients undergoing instrumented PLF and at 12 months found equivalent fusion rates (76% local vs. 68% ICBG).

Despite the use of rigid instrumentation, the rate of pseudarthrosis is not insignificant with iliac crest autograft. Dimar recently published a retrospective review of 194 patients with degenerative lumbar disease who underwent single-level, instrumented lumbar fusion with iliac crest autograft. Evidence of bridging bone was assessed using plain radiographs and fine-cut computed tomographic (CT) scan with CT reconstructions. At 2-year follow-up, 84% of the patients had evidence of fusion defined as the presence of bridging bone on CT scan.²⁵

Autologous bone from alternate sites is also available for grafting. Sawin et al.³¹ found successful fusion in 296 of 300 posterior cervical cases (98.6%) using rib autograft, whereas iliac crest successfully fused 49 of 52 cases (94%). Donor site morbidity and other major complications were significantly less common in the rib autograft group compared with the iliac crest group. No study has directly compared the use of rib with ICBG in lumbar spine procedures, probably because lumbar procedures do not readily expose the ribs as they would for the thoracic spine.

Bone Marrow Aspirate

Bone marrow aspirate is an alternative autologous graft material with inherent osteogenic and osteoinductive capabilities. It may be obtained readily from the anterior or posterior iliac crest by open or percutaneous routes. There are multiple commercially available bone marrow aspiration sets available. Bone marrow aspirate is highly cellular, containing large populations of stem cells with osteogenic capability. The aspirate also contains concentrated volumes of osteoinductive growth factors. Bone marrow aspirate, however, is neither an osteoconductive nor a structurally capable material and so is typically used in conjunction with products that are osteoconductive and/or structurally capable, such as autograft, allograft, DBM or other extenders. A comparison of bone marrow obtained from both the iliac crest and vertebral body through posterior aspiration of 21 patients by McLain et al.³² found that the vertebral body had a much higher concentration of bone progenitors than iliac crest, making it a more useful site for aspiration.

Neen et al.³³ examined BMA combined with a type 1 collagen/HA matrix (Healos) as an alternative to ICBG in a prospective case-controlled study of both posterolateral and interbody fusion. For posterolateral lumbar fusions, there were equivalent radiologic fusion rates for the two groups with no significant difference in the subjective and objective clinical outcomes. The radiologic fusion rate was significantly lower when Healos had been used for lumbar interbody fusions. Clinical outcomes for both groups were similar. There were no lasting complications associated with Healos use compared with a 14% persisting donor site complication rate in the autograft patients.

In a systematic review of cell-based therapies for spinal fusion, Khashan et al.³⁴ concluded that the available evidence, as of 2012, was insufficient to support the use of mesenchymal stromal cells (MSCs) or BMA combined with synthetic or allograft materials as a substitute or supplementary graft to autologous bone graft. This systematic review of the literature posed the following clinically relevant key questions (KQs):

1. Does the use of MSCs or BMA combined with synthetic or allograft extenders contribute to thoracolumbar fusion rates that are comparable to the rates achieved by the use of iliac crest graft?
2. Are these fusion rates comparable to those of LBG?
3. Is the addition of stem cells (SC) or BMA to ICBG or LBG contributes to better thoracolumbar fusion rates?
4. Are the cervical spine fusion outcomes achieved by the use of stem cell matrix (SCM) or BMA with synthetic or allograft scaffolds comparable to the ICBG or LBG outcomes?
5. Was there any difference in terms of fusion rates, when MSCs were used as compared to BMA?

For KQ1, four level II and III studies used ICBG as control. The results of these studies were inconsistent, and the overall body of evidence was found insufficient. Three level II and III studies were identified for KQ2. Comparable fusion rates were demonstrated between LBG and BMA combined with calcium phosphate or collagen carrier. The overall body of evidence was found weak. For KQ3, one level III study was found. No significant difference was found in the fusion rates. No studies met the criteria for KQs 4 and 5.

■ ALLOGRAFT

Cadaveric allograft is a common choice for use for interbody fusions in the cervical and lumbar spine, but it is

limited in terms of the ideal bone graft characteristics. The architecture of allograft creates a natural osteoconductive scaffold. Allograft also demonstrates good osteointegrative capabilities at the host-recipient interface. By nature of allograft processing, osteogenic cells are largely unavailable. Osteoinductive properties fluctuate depending on the preparation method, but are generally inconsistent and poor.

Allografts are available as fresh, frozen or freeze-dried preparations. Fresh allografts are not routinely used because they may be quite immunogenic and are at greater risk of disease transmission. Frozen allografts are primarily prepared by freezing, whereas freeze-dried allografts are prepared by freezing, and then dehydrating to approximately 25% of water. Further processing is performed with either ethylene oxide or gamma irradiation to make allografts safer with regard to immunogenicity and disease transference. This processing, however, reduces the osteoinductive capabilities, structural strength, and osteointegrative ability to varying degrees. Gamma irradiation tends to affect mechanical integrity more, whereas ethylene oxide affects the osteoinductive capabilities. Frozen allografts are more immunogenic and have a shorter shelf-life than freeze-dried, but freeze-dried allografts have less structural strength and less osteoconductive capabilities.^{35,36}

Allograft is available as cortical, cancellous or corticocancellous graft. Forms include powder, chips, wedges, pegs, dowels, or struts. Allograft can be machined and custom shaped if necessary. Cancellous graft is traditionally incorporated by endochondral ossification through the allograft scaffold with minimal initial strength that increases over time. In contrast, incorporation of cortical graft is by creeping substitution by way of intermembranous ossification within initial inherent structural strength, which weakens with resorption, eventually strengthening with bone deposition and organization.⁸

Complications with allograft use include graft fracture, lack of integration with surrounding peripheral bone, and infection. Transference of viral parts is also a potential concern. Reported rates of disease transmission are one in 1.6 million with fresh frozen and one in 2.8 billion with freeze-dried allograft. In spine surgery, there is only one reported case of HIV transmission.²⁷

In a prospective cohort study of 20 patients undergoing instrumented PLF, ICBG, frozen allograft, freeze-dried allograft, and a mixture of allograft and autograft were compared. There was a 0% fusion rate for freeze-dried allograft alone, and an 80% fusion rate with ICBG at 24 months.

Fresh frozen allograft has also been compared to ICBG for posterolateral instrumented lumbar fusion in 69 patients, with clinical outcomes being equivalent at 6 years. Radiological fusion rate was not reported in this study.³⁷

The efficacy of freeze-dried allograft in adolescent idiopathic scoliosis (AIS) fusion has been shown. Knapp et al.³⁸ retrospectively reviewed 111 patients at 5 years, with a combination of freeze-dried allograft chips and local autograft consistently achieving a 97% fusion rate. Jones et al.³⁹ also reported fusion rates of 93% in 55 patients with use of freeze-dried allograft chips and local autograft at 3-year follow-up.

Allograft is also used as a structural interbody graft in the cervical and lumbar spine. Both fresh frozen and freeze-dried forms are used. Miller et al.⁴⁰ reported a systematic review of safety and effectiveness of bone allografts in anterior cervical discectomy and fusion (ACDF) surgery. The primary aim of this review was to evaluate clinical and radiographic outcomes in studies of ACDF using allograft versus ACDF with autograft, ACDF with cage devices and cervical disc arthroplasty for the treatment of symptomatic cervical disc disease. After applying strict inclusion criteria, 21 comparisons from 20 studies formed the basis for this review. Patient outcomes included neck and arm pain, neck disability index, physical component summary and mental component summary scores from the Short Form 36 (SF-36), radiographic fusion rate and select adverse events (e.g. wound infection, dysphagia, and adjacent segment degeneration). The four treatment groups included ACDF with allograft (allograft, $n = 1341$), ACDF with autograft (autograft, $n = 568$), ACDF with cage (cage, $n = 87$), and cervical disc arthroplasty (arthroplasty, $n = 603$). Neck pain was reduced similarly by 63–69% in all groups. Comparable improvements were realized in arm pain after ACDF with allograft (75%) or arthroplasty (73%) that were greater than other treatment groups (62–68%). There was notable improvement in neck disability (61–65%) with allograft and arthroplasty after treatment. Physical component summary scores improved with allograft (42%) and arthroplasty (44%). Mental component summary scores improved modestly (16–21%) with allograft and arthroplasty. Fusion rates were 91% for allograft and autograft and 97% for cage. Adverse events were uncommon in all groups.

Given the nature of allograft and its preparation, many have expressed concerns about the biological robustness of this graft alternative in patients who smoke. Luszczek et al.⁴¹ examined the effect of smoking on the success of

single-level ACDF using allograft and a rigid plate. This study is composed of patients from the control groups of five separate studies evaluating the use of an anterior cervical disc replacement to treat cervical radiculopathy. For each of the five studies, the control group consisted of patients who underwent a single-level ACDF with allograft and a locked cervical plate. The authors reviewed data of 573 patients; 156 patients were smokers and 417 were nonsmokers. A minimum follow-up period of 24 months was required for inclusion in this study. Fusion status was assessed by independent observers using lateral, neutral, and flexion/extension radiographs. An overall fusion rate of 91.4% was achieved in all 573 patients. A solid fusion was shown in 382 patients (91.6%) who were nonsmokers. Among patients who were smokers, 142 (91.0%) had radiographic evidence of a solid fusion.

Thalgott et al.⁴² compared fresh frozen and freeze-dried allograft used as a structural interbody graft in 50 patients undergoing circumferential lumbar fusion. At 24 months, there was a greater fusion rate seen with fresh frozen allografts (65% freeze-dried vs. 77% fresh frozen). Overall clinical outcomes were equivalent between graft options.

In a prospective randomized study, Putzier et al.⁴³ compared ICBG with freeze-dried allograft chips for single-level posterior instrumented lumbar interbody fusion. The radiological outcome was based on both fusion rate (radiographs, computed tomography) and the bone mineral density of the grafts. After 6 months, the X-rays of the patients with allograft showed significantly lower rates of fusion. After 12 months, radiological results showed a similar fusion rate in both groups.

In a prospective study of 144 patients undergoing PLF, Jorgenson et al.⁴⁴ compared ICBG alone, ICBG mixed with ethylene oxide-treated allograft and ethylene oxide-treated allograft alone. Patients served as their own controls by placing ICBG on one side of the spine and the composite on the other side. The authors found that ICBG was significantly superior at producing fusion radiographically compared with allograft alone and allograft mixed with ICBG.

■ DEMINERALIZED BONE MATRIX

Demineralized bone matrix is the allograft that has been crushed to a consistent particle size and decalcified. Subsequent processing reduces immunogenicity and the risk of disease transmission. The product maintains the osteoconductive feature of the original allograft through the

organized trabecular collagenous structure of type I collagen and noncollagenous proteins. Removal of the mineral from the allograft improves the potential, albeit variable osteoinductive capability.

The collagenous framework allows for new vessel ingrowth, the infiltration of mesenchymal and precursor cells and eventual bone formation. The osteoinductive growth proteins available in the extracellular matrix induce mesenchymal cells to differentiate into bone-producing cells, but this ability is variable depending on storage, processing and the inherent capability of the donor tissue. In practical terms, the apparent osteoinductive capacity of these materials is more related to the concentration of locally produced native growth factors in the collagenous framework. Demineralized bone matrix does not impart structural integrity, but is useful as a space filler and as a composite with other graft materials, such as harvested autograft, bone marrow, minerals and calcium sulfate.⁴⁵

Demineralized bone matrix is manufactured with various carrier vehicles, such as glycerol, starch, collagen and hyaluronic acid. Different forms include moldable paste, putty, strips, gel, freeze-dried powder and granules. The primary negatives of DBM are the inherently variable osteoinductive properties, the lack of structural integrity, carrier concerns, such as glycerol (The glycerol carrier has been implicated as the nephrotoxic agent in a rat model using Grafton DBM. Bostrom et al. implanted rats with very high doses of and on autopsy found that the rats had died from hemorrhagic nephrotoxicity) and possible disease transmission compared with standard autograft.⁴⁶ Osteoinductive capacity is relatively low, and the variability is found, not only between the different manufacturing companies but also in products from the same manufacturer.

Wang showed that commercially available DBMs have highly variable osteoinductive potentials in a rat model. Comparing Osteofil, Grafton, Dynagraft and ICBG, fusions were assessed at 2, 4, 6 and 8 weeks postoperative with plain radiographs, manual palpation and histology after a PLF. Osteofil and Grafton showed significantly higher rates of fusion at all time points compared to Dynagraft and ICBG.^{47,48}

Bae et al.⁴⁸ quantified concentrations of BMP-2 and BMP-7 in a single DBM product and found significant lot-to-lot variability, not only in BMP concentrations but also in *in vivo* rates of fusion in a rat model. Fusion rates correlated positively with BMP-2 and BMP-7 concentra-

tions in a dose-dependent manner. They also found that the concentrations of BMP-2 and BMP-7 were one million times less than concentrations required for fusion clinically.

In a multicenter prospective study of 120 patients undergoing posterolateral spine fusion, Grafton gel-DBM combined with autologous ICBG was compared to autologous ICBG alone.⁴⁹ The composite graft was placed on one side and ICBG alone was placed on the contralateral side. Fusion rates were similar in the composite group (52%) and autologous graft alone groups (54%). You will have noticed that these reported fusion rates are relatively low compared to the rest of the literature, likely a result of very strict radiographic criteria for fusion.

Vaccaro et al.⁵⁰ studied 73 patients undergoing posterolateral instrumented lumbar fusion and reported that a composite of DBM Grafton Putty and BMA produced fusion rates similar to ICBG alone (63% Grafton Putty and BMA vs. 67% ICBG). Cammisa et al.⁵¹ prospectively compared DBM Grafton and ICBG to ICBG alone in 120 patients undergoing instrumented PLF. At 24 months, fusion results were equivalent (52% vs. 54%), although the study had a 30% rate of lost to follow-up.

In a retrospective study by Vaidya et al.⁵², DBM with allograft spacers demonstrated comparable fusion rates, cervical Oswestry scores, Visual Analogue Scale (VAS) for arm pain and neck pain, and radiographs as compared with recombinant human BMP 2 (rhBMP-2) and PEEK cages in 46 patients who underwent instrumented ACDF. Demineralized bone matrix and allograft spacers seem to be a safe and effective graft alternative to rhBMP-2 and PEEK cages for ACDF surgery, due to fewer side effects, cheaper cost and comparable fusion rates.

Aghdasi et al.⁵³ performed a systematic review of the English-language literature examining the efficacy of DBM in spinal surgery. Only original research articles in peer-reviewed journals that investigated fusion outcomes were included. Scientific validity of articles was appraised using the PRISMA methodology. Study design, DBM type, outcomes and results were reported. Primary outcome of interest was fusion rate. Secondary outcomes included Oswestry Disability Index (ODI), SF-36 survey and pseudarthrosis and surgical failure rates. They identified few prospective randomized controlled trials comparing DBM to autologous ICBG in spine fusion. The highest level of evidence studies have been performed using DBM in posterolateral lumbar fusion and suggest that DBM can be used successfully as a graft extender. In these studies, DBM

has been successfully combined with iliac crest autograft, local bone autograft and bone marrow to facilitate fusion. Grafton, which is a DBM product with a glycerol carrier, has been the most extensively studied DBM to date and success in prospective clinical studies has been observed with gel, putty and matrix formulations. Several case series support the use of DBM in the cervical spine although prospective controlled trials are lacking. They concluded that although the literature appears to support the use of certain DBM formulations in spine fusion surgery, further randomized controlled trials are necessary to fully understand the potential of different DBM products and the appropriate clinical scenarios for their use.

MINERALS

Hydroxyapatite

Hydroxyapatite is a crystalline structure and the basic component of the mineral state of bone. Its composition differs between the different mineral precursors, calcium phosphate and tricalcium phosphate. These compounds have a three-dimensional framework similar to bone and so have osteoconductive and osteointegrative capability. Although such agents may have initial structural integrity, they are eventually remodeled and replaced by immature and finally mature woven bone. Because of the absence of cellular or growth factor components, they lack any inherent osteoinductive or osteogenic capacity. They have different fabrication techniques, crystallinity, pore dimensions, mechanical properties and resorption rates. They are clinically attractive bone graft alternatives because of being non-immunogenic, unlimited in supply, easily sterilized and readily stored. Disadvantages include their brittle structure and low tensile strength.^{35,54}

Similar to the three-dimensional framework of bone, these highly porous compounds act as scaffolds allowing fibrovascular ingrowth, inward migration of bone-producing cells and spongy or immature bone deposition. Mineralization and remodeling occurs with eventual replacement by mature bone. These agents are available in paste, putties, solid matrices or granular form.

Coralline Hydroxyapatite

Coralline hydroxyapatite (CHA), derived from marine coral, is the sterilized calcium carbonate, which, although highly porous and regular, is very brittle and quick to resorb. Commercially available CHA is processed with

ammonium phosphate and sterilized, thus converting it to crystalline HA.⁵⁵ This product comes in granules or block form and has been combined with autograft, BMA and BMPs.

Lee et al.⁵⁶ reported on a retrospective review of 32 patients undergoing combined posterolateral and posterior lumbar interbody fusion with CHA and local autograft or ICBG alone. They found no differences in the rate of PLF (87% fusion for CHA and local autograft vs. 89% fusion for ICBG).

In a prospective evaluation of 57 patients undergoing PLF, Korolessis et al.⁵⁷ compared ICBG, CHA and BMA. At 12 months, they found that only ICBG had achieved fusion and recommended that CHA not be used alone for PLF in the lumbar spine.

Hsu et al.⁵⁸ reported mixed results with the use of CHA and laminectomy-derived bone as an adjuvant graft material for lumbar PLF. This prospective, case-control study involved 58 patients who underwent lumbar instrumentation-augmented PLF for degenerative spinal stenosis-induced segmental instability. The patients were divided into three groups. Laminectomy bone and anterior iliac crest bone graft (AIBG) were placed in the right intertransverse process space in group 1 (20 patients), CHA and AIBG were placed in group 2 (19 patients) and laminectomy bone and CHA were placed in group 3 (19 patients). Pure autogenous iliac cancellous bone graft was placed in the left intertransverse process space in all the three groups of patients. Successful fusion was determined by two spine surgeons after examining the plain, anteroposterior, bilateral oblique and lateral flexion-extension radiographs. If the examiners did not agree on fusion status, fine-cut CT scans of the fusion mass were used to make the final decision. They found that pure AIBG placed in left intertransverse process space was associated with the best fusion rate. After 6 months, CHA produced a comparable result to laminectomy-derived bone when combined with AIBG. When laminectomy bone was mixed with CHA, the combination failed to yield a satisfactory fusion rate (57.9%) even 1 year after surgery, if no AIBG was added.

The brittleness and poor structural integrity of CHA was demonstrated by McConnell et al.⁵⁹ in a prospective randomized comparison of CHA with autograft in cervical interbody fusion. In this study, 29 patients undergoing anterior cervical fusion and plating were randomized to receive either ProOsteon 200 structural CHA graft or iliac crest tricortical grafts. The SF-36 and ODI were used to measure clinical outcome. Postoperative radiographs

were analyzed for graft fragmentation, loss of height, angular alignment and hardware failure to assess structural integrity of the graft material. Plain radiographs and CT scans were used to evaluate fusion. Both the ProOsteon 200 and iliac crest groups demonstrated significant improvement in clinical outcome scores. There was no significant difference in clinical outcome or fusion rates between the two groups. Graft fragmentation occurred in 89% of the HA grafts and 11% of the autografts ($p = 0.001$). Significant graft settling occurred in 50% of the HA grafts, as compared with 11% of the autografts ($p = 0.009$). One patient in the ProOsteon 200 group required revision surgery for graft failure. The authors concluded that ProOsteon 200 does not possess adequate structural integrity to resist axial loading and maintain disc height or segmental lordosis during cervical interbody fusion.

Ceramics

The synthetic minerals HA and beta-tricalcium phosphate (β -TCP) are calcium phosphate-based ceramics. These ceramics are similar in structure to mineralized bone and so are highly osteoconductive and osteointegrative. Clinically usable ceramics are produced by heating to between 700°C and 1300°C to form the crystallized substance. While this improves compressive strength, the downsides are that it renders the material brittle (poor tensile strength) and very slow to resorb *in vivo*. These compounds are extremely porous, allowing direct fibrovascular invasion and eventual bone deposition. During the resorptive phase of graft incorporation, a portion of the tricalcium phosphate undergoes conversion to HA.^{60,61}

In general, tricalcium phosphate-based products are more porous and resorb at a quicker rate (12–24 months) than HA-based graft options (24–36 months). However, they are also mechanically weaker in compression than HA. There are several commercially available ceramic agents. Both HA and tricalcium phosphate ceramics are available in granules, block, poly or putty forms. Both have compressive strengths similar to cancellous bone and are brittle with poor resistance to shear.^{62,63}

Dai and Jiang,⁶⁴ in a prospective study of 62 patients undergoing PLF with β -TCP and local autograft, found 100% fusion rates on plain radiographic assessment at 3-year follow-up in both groups.

Ransford et al.⁶⁵ reviewed 341 patients undergoing fusion for AIS and noted equivalent fusion rates with less wound healing issues with the β -TCP group compared to the ICBG group.

Linovitz and Peppers⁶⁶ prospectively followed seven patients who underwent either anterior or posterior lumbar interbody fusion. A combination of β -TCP, freeze-dried cancellous allograft and venous blood was used. They reported 100% fusion rates in the 12 levels that were fused.

Silicate-Substituted Calcium Phosphates

Silicate-substituted calcium phosphates have recently gained more attention as an effective bone graft enhancer. Actifuse is composed of 0.8% silica-substituted HA and calcium phosphate. Silicone has been shown in *in vitro* studies to have osteogenic properties. It has a 35–50% porosity, and the silicone allows for a different composition, geometry and surface charge. Jenis and Banco⁶⁷ published a case series of 42 patients undergoing instrumented PLF. Actifuse was combined with BMA obtained from iliac crest, and fusion rates of 35% at 6 months postoperative and 77% at 24 months postoperative were reported.

Nagineni et al.⁶⁸ performed a retrospective analysis of a prospectively collected patient database including 108 patients (204 individual spinal levels). Different surgical procedures performed included 25 ACDFs, 17 posterior cervical fusions, seven combined anterior and posterior cervical fusions, 10 thoracic fusion surgeries, 18 transforaminal lumbar interbody fusions with 12 axial lumbar interbody fusions, 11 transposas discectomy and fusions and eight combined thoracolumbar fusion procedures. Silicate-substituted calcium phosphate was used as bone extender without any additional graft material, BMA or BMP. At a follow-up of 12 (± 4.7) months, 90% of all patients demonstrated radiographical fusion. Fusion rates were highest in the cervical spine (97%) followed by thoracic and lumbar spines (86% and 81%, respectively). There was no radiographical loosening of instrumentation due to infection or nonunion in this series, and no subsequent revisions for nonunion were required.

Composites

These products are often used as expanders for bone autografts combined with bone marrow and as carriers for osteoinductive BMP. There are many composite products available, including those with collagen, HA and tricalcium phosphate, combined with autograft, allograft or BMPs.

Epstein⁶⁹ prospectively evaluated Vitoss (80% tricalcium phosphate and 20% type 1 collagen)/BMA combined with local autograft in performing instrumented one-level ($n = 27$) and two-level ($n = 13$) posterolateral lumbar fusion. By 6 months, 96% of the one-level and 85% of the two-level patients were solidly fused. Epstein⁷⁰ also studied the use of Vitoss/BMA combined with local autograft in noninstrumented one- and two-level posterolateral lumbar in the geriatric population (i.e. average age of 70 years), with a reported fusion rate of 85% at 2-year follow-up.

Yamada et al.⁷¹ developed a hybrid graft (HBG) of porous β -TCP ceramic/percutaneously harvested bone sticks/autologous BMA for lumbar PLF. Sixty-one consecutive patients underwent decompressive laminotomy and one-level instrumented PLF. Each patient in this study had the constructs of the HBG placed on one side of the intertransverse process gutter. An autologous LBG harvested during decompressive laminotomy was placed on the other side as a control. Radiographic evaluation was performed at 6 months, 1 year after surgery and subsequently on an annual basis. The fusion statuses on either side of vertebra were compared. The flexion-extension motion in the dynamic X-rays at the target level decreased over time. Only one case exhibited over 5° of angular motion 2 years after surgery. In the evaluation of fusion status, the fusion rate for the HBG side (68.9% at 6 months, 83.6% at 1 year, 93.5% at 2 years) was higher than that for the LBG side (49.2% at 6 months, 75.4% at 1 year, 89.1% at 2 years) with a significant difference at 6 months after surgery. No significant complications at the donor site were found postoperatively.

CEMENTS

Cements were developed to improve the malleability and moldability of calcium phosphate bone substitute. Calcium phosphate-based cements crystalize to a carbonated HA that maintains a similar structure to the mineral phase of bone.⁷² Because of these unique properties, it may be conveniently injected to fill a bone defect (vertebroplasty) or to augment a screw fixation. Their inner strength lies in their osteoconductive and osteointegrative capabilities, as well as their immediate compressive strength once set. These compounds are available as injectable liquid or moldable putty and set with an isothermic reaction. They resorb by disilusion and osteoclast resorption. Disadvantages include weakness in torsion and shear. One very significant concern is the potential extrusion of cement into

soft tissues or into the spinal canal, thus potentially damaging and creating a neurological deficit. These materials are not routinely used as bone graft substitutes.

CALCIUM SULFATE

Calcium sulfate (CaSO_4 ; plaster of Paris) has been available as a void filler for more than 100 years. It is heated gypsum and when made into powder form has a crystalline microstructure. It is primarily osteoconductive in nature, with better compressive strength than cancellous bone, but poor tensile strength. Primary drawbacks include inconsistency in crystalline structure during setting and rapid resorption by dissolution of the product, which may create an imbalance between bony replacement and resorption.

Calcium sulfate is a completely resorbable, biocompatible BGE. It is quickly resorbed, usually within 6–8 weeks, but has been implicated in causing postoperative wound drainage problems due to an excessive inflammatory reaction.^{73,74} Ziran et al.⁷⁵ reported a 51% wound drainage and 30% infection rate following use of calcium sulfate in treating tibial nonunions. Chen et al.⁷⁶ prospectively reviewed 74 patients who underwent PLF with calcium sulfate and local autograft. At 33-month follow-up, they showed equivalent fusion rates with ICBG (87% calcium sulfate and local autograft vs. 90% ICBG). Niu et al.⁷⁷ had far worse results with the use of calcium sulfate in 43 patients undergoing PLF. At 12-month follow-up, there was a 45% fusion rate with calcium sulfate and BMA compared to ICBG alone.

The breadth of calcium sulfate products has widened to include calcium sulfate mixed with other bone substitute products, DBM and antibiotics (Osteoset).

BIOACTIVE GLASS

Bioactive glass is a solid material composed of sodium oxide, calcium oxide, silicon dioxide and phosphorus. Bioactivity, the interaction between host bone and the graft, depends on the silicon content of the glass. These agents demonstrate strong host graft bonding as the silica breaks down after exposure to host fluid forming a calcific layer from which HA has been laid down. This results in a strong integrated response of the tissue agent interface, creating an enriched osteoconductive environment. Advantages of BAG include its strong and unique bonding capability, osteoconductive properties, ability to modify the composition, possible osteostimulation and good resorption. However, BAG offers little structural support. The product

is available as microspheres, fibers, paste and porous implants. These agents may be injected into a defect or molded into putty.^{78,79}

Acharya et al.⁸⁰ evaluated the efficacy of HA-bioactive glass ceramic composite (Chitra-HABg) as a stand-alone graft substitute in promoting PLF in the lumbar spine as compared with autologous bone. Twenty-four patients underwent instrumented PLF, with Chitra-HABg laid on the left intertransverse bed and autogenous graft on the right side. The primary outcome measure was radiologic consolidation of the graft, and secondary outcome measures were the work status and the modified ODI. Although the study was prematurely terminated owing to the high incidence of resorption of Chitra-HABg, 22 of the 24 subjects were followed up for a minimum of 1 year. At the end of 1 year, excellent radiologic outcome was seen on the right side (autogenous graft) in all the cases, whereas 95% (21/22) of the cases had poor consolidation on the left side (Chitra-HABg). This study clearly demonstrates that Chitra-HABg has no role as stand-alone bone graft substitutes in PLF of the lumbar spine, as the composite undergoes resorption without the formation of bridging callus.

Rantakokko et al.⁸¹ performed a prospective long-term follow-up study of BAG-S53P4 and AB used as bone graft substitutes for posterolateral spondylodesis in treatment of unstable lumbar spine burst fractures. The lumbar fractures were fixed using posterior universal spine system (USS) instrumentation. Bioactive glass was implanted on the left side of the fusion bed and AB on the right side. A solid bony fusion was seen on CT scans on the side of the AB implantation in all 10 patients. Resorption of the implanted graft was mild ($n = 7$) or absent ($n = 3$). On the BAG implantation side, a solid fusion on CT scans was only seen in 50% of patients. Resorption of BAG was mild ($n = 3$), moderate ($n = 2$) or evident ($n = 5$). Bioactive glass granules were still partially visible in six out of 10 patients on CT scans.

Abdullah et al.⁸² performed a systematic review to evaluate the available literature supporting the use of lumbar fusion extenders in clinical practice. A review of English-language literature was performed between 1990 and January of 2010 for all literature presenting clinical outcomes of lumbar fusion extenders. After controlling for inclusion and exclusion criteria and assigning levels of evidence, 19 clinical studies were fully reviewed including those for DBM, rhBMP-2, f3-TCP and calcium sulfate. The investigators found that the most extensively studied of the lumbar fusion extenders is β -TCP, especially with

regard to its use in adolescent scoliosis correction. The use of rhBMP-2 and DBM as extenders was supported only by two and three clinical studies, respectively. Calcium sulfate and other miscellaneous extenders were not conclusively or consistently supported by available clinical studies.

Alsaleh et al.²⁸ performed a systematic review to evaluate the efficacy, safety and outcomes of osteoconductive BGEs compared with ICBG in posterolateral thoracolumbar spinal fusion. An electronic literature search was conducted through April 2011 using MEDLINE, EMBASE, CENTRAL and Cochrane Library. Risk of bias and methodological assessment was performed. Study design and result heterogeneity was also analyzed. Pooled weighted relative risk (RR) ratios were calculated to compare fusion and adverse event rates. Weighted standardized mean differences were calculated to compare functional outcome and pain scores. Thirteen studies were included representing a total of 768 patients. Overall study quality was low (mean Cochrane Risk of Bias score, 4.8 out of 12; range: 3–6). Fusion rates were comparable between the BGE and ICBG groups (RR = 0.96; 95% confidence interval [CI]: 0.89–1.03; $p = 0.28$). There was substantial heterogeneity in the pooling of studies. The pooled rate of donor site pain in the ICBG group was 11.2% (95% CI: 7.4–15.1%). Reported adverse events, excluding donor site pain, were significantly lower in the BGE group (RR = 0.42; 95% CI: 0.28–0.64; $p < 0.0001$). Functional outcomes were not significantly different between the two groups. The authors concluded that osteoconductive BGEs combined with local spine autograft and/or BMA have comparable fusion rates, similar functional outcomes, lower complication rates and a lower risk of donor site pain than ICBG. Caution should be taken in interpreting these findings, given the low quality of the studies and the heterogeneity in the results. Randomized controlled studies using blinded assessments are required to help elucidate more conclusive evidence.

OSTEOPROMOTIVE AGENTS/GROWTH FACTORS

Bone repair and spinal fusion are highly orchestrated processes involving myriad growth factors. These proteins may be produced locally at the site of bone formation or may be delivered by chemoattracted circulating cells such as the lymphocyte, the platelet and the macrophage. While myriad growth factors have been implicated in the process of spinal fusion, only two are currently clinically available.

These are the BMPs, 2 and 7 and PRP. The BMPs are the focus of another chapter in this textbook, and so will not be discussed here.

Platelet-rich plasma is defined as a portion of the plasma fraction of autologous blood having platelet concentrations above baseline. When activated, the platelets release growth factors that play an essential role in bone healing such as PDGF, TGF- β , VEGF and others. Multiple basic science and in vivo animal studies agree that PRP has a role in the stimulation of the healing cascade in ligament, tendon, muscle cartilage and in bone regeneration. However, the results of clinical studies in spinal fusion have been less than encouraging, and currently there is no evidence to recommend their use in routine clinical practice.

Sys et al.⁸³ examined the efficacy of PRP in monosegmental posterior lumbar interbody fusion. Forty patients were recruited for the study fulfilling strict entry requirements and were randomized with a 1:1 ratio. In each group, one patient was lost to follow-up. Thirty-eight patients completed the VAS, the ODI questionnaires and the SF-36 preoperatively and postoperatively at 3, 6, 12 and 24 months, respectively. Computed tomographic scans of the lumbar spine were taken at 3, 6 and 12 months. Posterior stabilization was achieved with pedicle screws and interbody fusion was aimed at with carbon cages filled with autologous bone. Baseline demographic data (age, sex, smoking history, preoperative outcome measures) showed no relevant difference between groups. For patients who received autograft only, the mean VAS improved by 4.0 points ($p < 0.01$), mean ODI improved by 32.1 points ($p < 0.001$) and mean SF-36 showed statistically significant improvement in each of the eight domains and in the physical ($p < 0.001$) and mental ($p < 0.001$) component summary measures. For patients who received autograft with PRP, the mean VAS improved by 4.92 points ($p < 0.01$), mean ODI improved by 30 points ($p < 0.001$) and mean SF-36 showed statistically significant improvement in six of the eight domains ($p < 0.02$) and in the physical ($p = 0.016$) and mental ($p < 0.001$) component summary measures. The improvement in the VAS score and the physical component summary score was more pronounced in patients who received autograft with PRP. These differences were, however, not statistically significant. Computed tomographic scans showed uneventful osseous healing in all but one patient with no difference between groups. In this prospective randomized controlled clinical and radiological trial, adding PRP in posterior lumbar interbody fusion did not lead to a substantial improvement or

deterioration when compared with autologous bone only. No inhibitory effect of PRP was observed on CT scans. The authors concluded that from a clinical and radiological point of view, the use of PRP seems to be justified in posterior lumbar interbody fusion surgery. From an economical point of view, however, the expense of using PRP cannot be justified until statistical significance can be reached in a larger study.

Acebal-Cortina et al.⁸⁴ analyzed, if the adding of autologous platelet concentrate (APC) to a mixture of local autograft plus TCP and HA (TCP/HA) would improve the fusion rate in posterolateral lumbar fusion. They performed a prospective, controlled, blinded, nonrandomized clinical trial in 107 patients affected by degenerative lumbar pathology. The study group consisted of 67 patients, in which autologous platelet concentration was added to a mixture of autologous LBG and TCP/HA. A control group of 40 patients with same pathology and surgical technique but without APC addition was used to compare the fusion mass obtained. By means of plain X-rays, a blinded evaluation of the intertransverse fusion mass quality at 12 and 24 months was made according to type A (bilateral uniform mass), type B (unilateral uniform mass) and type C (irregular or lack bilateral mass). Patients with type C were regarded as pseudarthrosis. In the study group, 17 patients had lack or irregular fusion mass (25.4%) versus three patients in the control group (7.5%), which was statistically significant. This study shows that the adding of autologous platelet concentration to a mixture of autologous bone graft plus TCP/HA has decreased our rates of posterolateral lumbar fusion.

CELL-BASED THERAPIES

Cells are key players in bone regeneration. Osteoblasts produce osteoid, an extracellular protein-based matrix, which mineralizes to become bone. Osteoprogenitor cells or MSCs can differentiate into osteoblasts and induce bone formation. Currently, two ways exist to prepare cells for clinical application, each with their advantages and disadvantages. One method is to concentrate cells immediately in the operating room and place them directly on the site of injury. Unfortunately, only low cell numbers can be generated by this process. Another method is to expand the cells in vitro. By this method, a very large number of cells can be generated. The two-step method has two disadvantages: one additional exposure to anesthesia is

required for reimplantation of the cells, and there is a risk of an *ex vivo* cell dedifferentiation and infection during the cell expansion.

Currently available cell-based bone graft substitutes include BMA and MSCs. These options lack osteoconductive or structural material properties and so must be used in combination with biological scaffolds (allografts and autografts) or with synthetic carriers. Bone marrow aspirate contains osteoprogenitor and hematoprogenitor cell populations. It is easily obtained from the posterior iliac crest and from vertebral bodies. The paucity of evidence for the use of BMA has already been discussed.

Mesenchymal Stem Cells

Stem cells have two essential fundamental characteristics: the ability for self-renewal and the ability to differentiate into a variety of cell phenotypes. Stem cells are loosely categorized as being either adult or embryonic depending on their origin. The bone marrow contains both MSCs and hematopoietic stem cells. The latter have been used clinically for many years, predominantly in the treatment of hematological malignancy. Iliac crest bone grafting is a form of autologous MSC transplantation. Autologous transplantation of MSCs has a similar potential for donor site morbidity, with an additional major issue being that, following harvest, the cells require *in vitro* expansion. This introduces added cost of individual culture expansion, regulatory hurdles and logistical impediments, as surgery using these cells is delayed by several weeks from the time they are harvested. Furthermore, autologous cells are of variable quality depending on the protoplasm of the patient.^{85,86}

Allogeneic cell transplantation overcomes these problems, as an “off the shelf” product, with batch-to-batch consistency, can be used as needed. The potential for transmission of infection and rejection are the obvious concerns of an allogeneic approach; however, donor screening and extensive testing of the cells, in a similar manner employed for blood transfusions, minimizes the infection risk. The rejection risk is minimal as mesenchymal cells are of low immunogenicity.

Mesenchymal stem cells can be isolated from various tissues and under the correct *in vitro* culture conditions can be preferentially differentiated into an osteogenic lineage of cells that produce osteoid.⁸⁶

Khashan et al.³⁴ performed a systematic review of the literature attempting to answer a number of KQs:

1. Does the use of MSCs or BMA combined with synthetic or allograft extenders contribute to thoracolumbar fusion rates that are comparable to the rates achieved by the use of iliac crest graft?
2. Are these fusion rates comparable to those of LBG?
3. Is the addition of stem cells (SC) or BMA to ICBG or LBG contributes to better thoracolumbar fusion rates?
4. Are the cervical spine fusion outcomes achieved by the use of SCM or BMA with synthetic or allograft scaffolds comparable to the ICBG or LBG outcomes?
5. Was there any difference in terms of fusion rates, when MSCs were used as compared to BMA?

In this systematic review, the authors found that clinical studies were only available for BMA and not for MSCs.

A recent preclinical study designed to assess the safety and efficacy of mesenchymal pluripotent stem cells (MPC)-facilitated cervical interbody fusion in a sheep⁸⁷ model showed no cell-related adverse events, including absence of swelling, airway compromise or neural compression. MPCs were added to a commercially available TCP/HA carrier and were demonstrated to promote a faster and more robust fusion than current clinical treatments using autograft or carrier alone.

Nakajima et al.⁸⁸ investigated the effectiveness of graft material for spinal fusion using a rabbit model by examining the MSC with or without osteogenic differentiation. Japanese white rabbits were divided into four groups: (1) autologous bone (AG), (2) HA, (3) MSC and (4) osteogenic MSC (OMSC). Each group underwent fusion of the intertransverse processes. The lumbar spine was harvested en bloc, and the fusion mass was evaluated radiographically, by manual palpation test and by histologic analysis at 6 weeks after surgery. Fusion success or failure was assumed based on the results from manual palpation of the harvested spine. Four of five rabbits in the OMSC group, four of six rabbits in the AB group, two of six rabbits in the MSC group and none of six rabbits in the HA group achieved fusion. In the OMSC group and AG group, new bone formation was observed histologically. In the HA group, fibrous tissue and cartilage were observed and there was no new bone. In the MSC group, less mature bone formation was present in the grafted fragments. The study suggested that MSCs that have been cultured with osteogenic differentiation medium may induce the formation of new bone in experimental spinal fusion.

Risbud et al.⁸⁹ evaluated the osteogenic potential of MSCs isolated from the bone marrow of the human vertebral body (VB). Marrow samples from VB of patients

undergoing lumbar spinal surgery were collected; marrow was also harvested from the IC. Progenitor cells were isolated and the number of colony forming unit-fibroblastic (CFU-F) determined. The osteogenic potential of the cells was characterized using biochemical and molecular biology techniques. Both the vertebral body (VB) and iliac crest (IC) marrow generated small-, medium- and large-sized CFU-F. Higher numbers of CFU-F were obtained from the VB marrow than the IC ($p < 0.05$). Progenitor cells from both anatomic sites expressed comparable levels of CD166, CD105, CD49a and CD63. Moreover, progenitor cells from the VB exhibited an increased level of alkaline phosphatase activity. Mesenchymal stromal cells of the VB and the IC displayed similar levels of expression of Runx-2, collagen type I, CD44, activated leucocyte cell adhesion molecule (ALCAM) and osteocalcin. The level of expression of bone sialoprotein was higher in MSC from the IC than the VB. VB and IC cells mineralized their extracellular matrix to a similar extent. These studies showed that CFU-F frequency is higher in the marrow of the VB than in that of the IC. Progenitor cells isolated from both sites respond in a similar manner to an osteogenic stimulus and express common immunophenotypes. Based on these findings, the authors propose that progenitor cells from the lumbar vertebral marrow would be suitable candidate for osseous graft supplementation in spinal fusion procedures. They suggested that studies must now be conducted using animal models to ascertain, if cells of the VB are as effective as those of the IC for the fusion applications.

Hormonal/Gene Therapy

Gene therapy is an interesting tool used to accomplish the local delivery of beneficial growth factors for bone regeneration. Genetic modification of cells can have advantages compared with the simple supplementation of cytokines or growth factors. First, the selected proteins have a short half-life. Second, a single administration is usually not sufficient for a biological effect. Third, the costs for the required quantities of protein would be prohibitively high. Fourth, continuous protein synthesis by genetically modified cells increases the likelihood for the desired effect. Genetically modified autologous MSCs, (over) expressing osteogenic growth factors or cytokines, provide both autocrine and paracrine stimuli to induce and maintain osteogenic differentiation and are therefore promising cellular components for protocols aimed at site-specific bone

repair. In addition, the systemic or intraosseous marrow reimplantation of autologous MSCs genetically “corrected” for any skeletal degeneration-causing mutation could help to solve problems of limited availability and suboptimal engraftment of allogeneic MSCs.⁹⁰⁻⁹³

There are both viral and nonviral methods to accomplish the above, with the viral methods showing a higher transfer efficiency of target genes. Currently, due to safety reasons, only animal models exist to evaluate gene therapy for fracture healing. An interesting method being developed for future clinical use is the ex vivo adenoviral transduction of tissue grafts to continuously deliver growth factors such as BMP-2 over a limited period needed for fracture healing.

In addition to local agents, the systemic use of hormone therapy in fracture healing is under investigation. Growth hormone appears to have a positive influence on fracture healing in animals and humans. Parathyroid hormone (PTH) has been shown to have a positive effect on fracture healing, especially for osteoporotic bones.

The latest large animal investigations have reported improved bone defect healing by local delivery of PTH. In addition to binding PTH to fibrin, incorporating PTH to biomimetic calcium phosphate coating also offers a potential option for future therapies in humans. At this time, hormone therapy for human fracture healing is only under off-label use as further investigation into the appropriate dosages and safety factors is still necessary.⁹⁴

Hirsch et al.⁹⁵ performed a systematic review to evaluate the available evidence on the potential impact of bisphosphonates and PTH on fusion rate and fusion quality in spinal arthrodesis. The literature contained 18 animal studies and one clinical trial investigating the impact of these medications on spine fusion. Most animal studies evaluating the impact of bisphosphonates on fusion rate have not found statistically significant changes with treatment, although this fact may be attributable to low statistical power. The animal literature does suggest that bisphosphonate therapy results in a less histologically mature fusion mass; however, the impact of these changes on fusion mass biomechanics is unclear. The only available human study suggests that these bisphosphonates may increase the radiographically defined fusion rate but did not demonstrate an impact on clinical outcome. In animals, PTH improves the fusion rate and fusion mass microstructure, but data on its effect on fusion mass biome-

chanics are lacking. No studies have evaluated the impact of PTH on spine fusion in humans.

CONCLUSION

This review provides the physician/surgeon with:

1. A clinically relevant review of the biology of spinal fusion and bone grafting,
2. A comprehensive consideration of the currently available bone graft substitute options and
3. A conceptual framework for the analysis and evaluation of future studies.

Although many of the studies reviewed here have shown at least equivalence of numerous bone graft substitute options to iliac crest, there is insufficient evidence to recommend them over the gold standard. For most products, the quality of the scientific evidence is low, with the bulk of the studies being retrospective case series or at best underpowered prospective cohort studies. Inconsistent study design and lack of proper control groups has meant that much of the published literature is not comparable, making meta-analysis impossible and systematic review challenging.

Vascularized Bone Grafts in Spine Surgery

Gregory Gebauer

Snapshot

» Indications

» Sources of Vascularized Autograft

INTRODUCTION

Achieving a solid bony fusion is necessary for the successful outcome of many complex, reconstructive spinal operations. The use of bone grafts is common in these procedures, both to help achieve a bony fusion and to provide structure support. There are many types of grafts, including local autograft, harvested bone graft obtained through a separate incision (such as iliac crest autograft), allografts and demineralized bone grafts. All of these have been shown to be effective and play an important role in surgery on the spine. However, in the setting of complex pathology, such as infection or spinal tumors, or in patients predisposed to poor bony healing, achieving such a fusion using these grafts can be difficult. The use of vascularized bone graft offers many advantages that may help to overcome these challenges.

Allografts and nonvascularized autografts are remodeled into a solid fusion by the process of creeping substitution. In this process, the bone is revascularized, reabsorbed by osteoclasts and finally remodeled into reactive bone. This process can take months or years and complete incorporation may never occur. Additionally, during the initial remodeling phases the grafts are structurally weaker due to the increased porosity of the bone.¹ It has been estimated that fatigue fractures occur in 16–20% of structural allografts^{2,3} and in up to 50% of anterior grafts over 4 cm in length.⁴ Vascularized autografts, by maintaining their blood supply, keep the osteocytes viable.⁵ This allows them to forego an extensive remodeling process and maintain their structural integrity.^{6–8} Additionally,

vascularized grafts respond to mechanical stress with hypertrophy, resulting in increased stiffness over time.^{9–11} The harvesting and placement of vascularized bone grafts is however technically demanding and can involve microsurgical techniques not familiar to most spine surgeons.

INDICATIONS

There are no clear indications for when a vascularized graft should be used. For most patients, standard bone grafting and surgical technique should be sufficient. Typically, patients requiring vascularized bone graft will have relatively unique and special circumstances that impair normal bone healing. Shin and Dekutoski suggested four indications:¹²

1. Multiple level corpectomy, typically for tumor resection.
2. Failed previous spine arthrodesis secondary to osteomyelitis or neurofibromatosis.
3. Poor osseous and soft tissue bed secondary to radiation exposure necrosis.
4. Failed fusion in neuromuscular disease, such as Charcot arthropathy.

For patients with spinal tumors, the prior use of radiation or the need for postoperative radiation for local tumor control has been shown to have a negative effect on graft incorporation and healing.

These recommendations are not, however, without some controversy. Bradford and colleagues have suggested that vascularized grafts should not be used in patients with tumors.^{13,14} Their concern is that the increased blood flow from the vascularized graft could supply the tumor

cells and lead to local recurrence or lead to metastasis if tumor cells carried through the blood stream. Others have argued that this is more of a concern during intralesion tumor excision and that there is less concern if tumor is removed en bloc.¹²

SOURCES OF VASCULARIZED AUTOGRAFT

Multiple sources of vascularized autograft have been described. These include the ribs,^{4,14} fibula,^{12,15} scapula,¹⁶ iliac crest,¹⁷ tibia,¹⁸ and distal radius.¹⁹ They have been utilized throughout the appendicular skeleton and in the head and neck to treat multiple different pathologies, including tumors, trauma, nonunions, osteonecrosis, and congenital defects.^{17,19-22} Rib and free fibula grafts are the most common donor site for vascularized grafts in spine surgery. The rib graft has the advantage of its close anatomical location to the spine. This allows the bone to be transferred on its vascular pedicle without the need for microsurgery. This also limits the location where the graft can be used to the thoracic spine and thoracolumbar junction. Additionally, the curved shape and thin size of the ribs mean that they may not always be appropriate for anterior strut grafting. Free fibula grafts offer better mechanical properties and can be placed anywhere within the spine; however, they require a microvascular anastomosis to reconnect the blood vessels and require a second surgical site for graft harvest.

Vascularized Rib Graft

The close location of the ribs and their vascular pedicles make the local transfer of the vascularized bone to defects in the thoracic spine possible. While the rib does not have the structural integrity to serve as an anterior strut graft, the vascularized bone can be used as an “on-lay” graft to supplement anterior fusion or for posterior fusion between the transverse processes.²³⁻²⁸ The curvature of the ribs may fit the nature kyphotic posture of the thoracic spine or may need contouring for optimal positioning.

Rib graft can be harvested from either the prone or the lateral position, depending on the exposure needed for the primary procedure. A wider area around the rib cage should be included in the surgical field; however, in most cases adequate graft can be obtained from the standard incisions used to approach the spine. The size of the defect requiring grafting should be measured. An additional

2–3 cm of graft should be planned to be harvested. The rib selected should be on the ipsilateral side as the defect or can be bilateral if a posterior approach is used. The rib selected should be either from the superior or inferior margins of the defect and may depend on the location of the defect. The most upper (1–4) and lower ribs (11 and 12) may not offer sufficient length for graft material. Generally, the middle ribs make for the best donor graft.

Once the rib is selected, the anterior point for the rib resection is identified. The intercostal vessels are ligated distal to this point. The anterior rib can then be cut. The rib is then mobilized from lateral to medial with care taken to preserve the intercostal vessels. Proximally, the vascular bundle is freed down to its connection to the aorta. This may require mobilizing the vascular pedicle from the most medial aspects to the rib, just lateral to the rib head to allow for better mobility. The medial rib is then separated at the rib head and rotated on its pedicle into the defect.

The graft can now be prepared to be seating into the defect. If necessary, unicortical cuts can be created on the concave portion of the rib using a small oscillating saw and allowing the graft to be straightened¹² (Fig. 33.1). Lewis et al. have described a technique for step-cut osteotomies for use in posterior grafting.²⁵ Using their method, a concave, saddle cut is made at the distal end of the graft that is seated on the pedicle at the inferior margin of the defect. A step-cut is then made at the proximal end. This is seated under the transverse process or lamina at the superior edge of the defect. Once positioned gentle compression can be used to secure the graft and posteriorly placed instrumentation can be used to help secure the graft in place.

Clinical Results—Rib Graft

The results of several case series using vascularized rib graft to augment fusion in reconstruction of the thoracic spine have been published. Wilden et al. reported on a series of 18 patients.²⁶ They reported that all the patients went on to fuse at average time of 6.8 months and that there were no complications related to the graft harvest. Lewis reported on a series of 17 patients using their step-cut technique.²⁵ Of these, 8 used vascularized rib grafts and 9 used nonvascularized grafts. Of the 8 patients with a vascularized rib graft, 4 died due to their underlying disease (cancer). The remaining 4 demonstrated graft integration and no loosening or subsidence at approximately 4 years from surgery.

Similar results are also available for anterior vascularized rib grafts. Govender et al. followed 8 children with Pott’s disease for a minimum of 10 years and reported

Fig. 33.1: Placement of vascularized rib graft for posterior spinal fusion. Note the cuts made along the bone to allow for straightening of the normally curved rib.

bone fusion in all cases.²⁷ Nakamura et al. reported on 23 adult patients with anterior vascularized rib graft.²³ In this series, the graft was folded on itself to form 3 or 4 pieces all connected on the same pedicle. They reported bony fusion in all cases without the use of additional bone graft or extenders.

Free Fibula Graft

The fibula has many features that lend to its suitability as a vascularized bone graft. The fibula can be harvested with minimal donor site morbidity. Its peripheral location makes harvest relatively simple. Its vascular pedicle is large enough (2–3 mm) to allow for the anastomosis. In addition, it is a relatively straight bone with excellent mechanical strength, allowing it to be used as a structural support.

Before performing a vascularized fibular graft, careful preoperative planning should be performed. This includes assessments of both the donor site and the recipient bed. At the recipient bed, a vessel capable of accepting

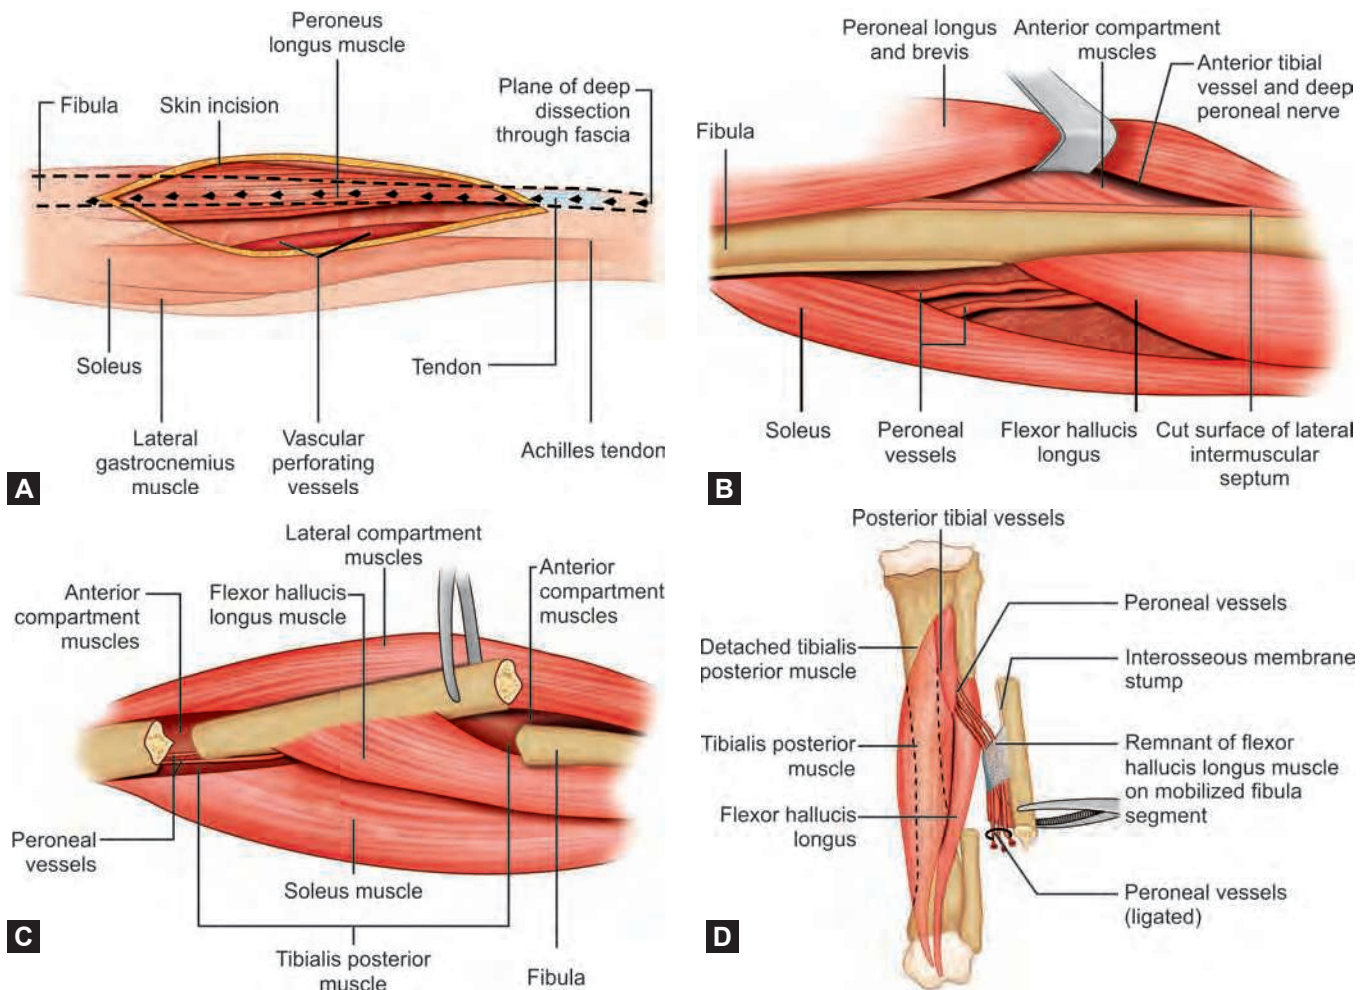

the anastomosis should be identified. This may require computed tomography (CT) or magnetic resonance (MR) angiography. The surgical approach should be selected to allow for access and visualization of both the spine and the anastomosis site. The length of the defect to be grafted should be measured as this will determine the amount of fibula necessary to harvest.

The donor site should also be carefully evaluated. The presence of abscess or any other injuries, infections or conditions that may affect the leg should be identified. The vascularity of the limb must also be assessed. Some authors have recommended the use of angiography for all patients being considered for this procedure.²⁹ Others rely first on physical examination.²⁰ In this technique, the presence and quality of both dorsal pedal and posterior tibial pulses is first checked. If one or both pulses are abnormal or absent, further evaluation by ultrasound or angiography is then performed. Finally, if there are no restrictions forcing the use of only one limb, the right or left side can be selected on the ease of access depending on how the patient is positioned during the surgery, i.e. if the patient is in the right-side decubitus position with the left side up then it is easier to harvest the left fibula.

The surgical technique for graft harvest has been well described by Woods and others (Figs. 33.2A to D).^{20,30,31} Once positioned for surgery, a tourniquet should be applied to the upper thigh. The remaining limb, from above the knee to the toes, should then be prepped and draped. The fibula should be marked along its entire length. The main nutrient artery is generally found between the junction of the middle and proximal third and the midpoint of the fibula. The incision should be centered at this point. The amount of graft necessary can then be measured. An additional 5–6 cm should be taken to ensure adequate bone harvest.

A linear incision is made along the length of the fibula and dissection carried out down to the fascia. The lateral and posterior muscle compartments are identified. In the distal portion of the incision, the peroneus longus tendon is identified. Posterior to the tendon a thin layer of adipose tissue can be seen. This marks the plane between the lateral muscle compartment and the soleus muscle in the posterior compartment. Several perforating vessels cross this plan. If an osteocutaneous flap is planned, these vessels should be spared. Otherwise they can be ligated.

Dissection is then continued proximally, identifying the soleus muscle. This can be elevated posteriorly off the fibula. Care should be taken as the peroneal vessels are

Figs. 33.2A to D: Surgical dissection of the vascularized fibula graft: (A) superficial dissections; (B) deep dissection, with care taken to identify and preserve the peroneal vessel; (C) lateral and (D) anterior diagrams of the harvested fibula graft and vessels.

located just deep to the proximal soleus. These vessels should be visible in the proximal incision after the soleus is detached. Attention is then returned to the distal portion of the incision. Here, the peroneal muscles are elevated. The flexor hallucis longus (FHL) muscle should be left in place to help protect the peroneal vessels until they can be identified and dissected later in the procedure. It is also important to identify and protect the superficial peroneal nerve during dissection of the peroneal muscles. If it is necessary to take the proximal fibula, the common peroneal nerve should be identified and protected. Once the peroneal muscles are separated, the septum between the lateral and anterior can be sharply incised and the anterior muscles elevated off the fibula and interosseous membrane. The anterior tibial vessels and the deep peroneal nerve lie within this plane and should be protected.

At this point, the planned length of fibula to be taken should be measured and marked. Care should be taken to include the middle third of the bone to ensure that the main nutrient artery is included within the segment to be harvested. The proximal osteotomy is created first. Retractors should be placed around the bone to protect the vessels and soft tissues. A gigli or small oscillating saw can be used. A small amount of the FHL muscle is then elevated in the area of the distal osteotomy. The retractors can then be placed, and the osteotomy again can be created with a saw.

An additional 1–2 cm of the FHL muscle should then be elevated. At this point, the fibula can be gently retracted anteriorly and the peroneal vessels should now be visible deep to the FHL muscle at the distal portion of the incision. The distal peroneal vessels can then be ligated and

sectioned. The fibula should then be externally rotated to expose the interosseous membrane. The membrane can now be released from proximal to distal revealing the tibia-lis posterior muscle. This muscle can be then elevated with care taken to preserve the peroneal vessels that lie deep into the muscle. The peroneal vessels should now be visible. Many arterial and venous branches should be visible. Any medially directed branches can be ligated. Any laterally or posteriorly directed branches or any branches that enter into the FHL muscle should be preserved. Except for the portion directed adjacent to the vessels, the remaining FHL can now be elevated.

At this point, the peroneal artery and veins should be isolated in the proximal incision. Additional mobilization of the vessels can be achieved by dissecting them off the proximal portion of the graft. Minor periosteal branches can be ligated, but care should be taken to preserve the main nutrient artery. In most cases, a pedicle length of 6–8 cm should be achievable. The proximal peroneal vessels should then be isolated with vessel loops. At this point, Wood recommends deflating the tourniquet and allowing the graft to reperfuse for at least 5–10 minutes or until the recipient site is ready.

Following harvest of the graft, the incision site is closed in standard fashion. The fascia can be left open to minimize the risk of postoperative compartment syndrome. Drains can be used at the surgeon's discretion. Some authors have advocated reconstruction of the fibular defect, either with beta-tricalcium phosphate³² or by bone grafting the site using any redundant portions of the fibula not used at the recipient site.³³ Both of these studies were limited in size (14 patients in the beta-tricalcium phosphate study and 10 in the experimental arm of the bone graft study). Arai et al. evaluated the use of beta-tricalcium phosphate using only radiograph and subjective measures.³² They reported bony union in only 2 of 9 adult patients and 3 of 5 pediatric patients. While none of the pediatric patients reported limitations, many of the adults reported problems with walking (4), running (11) or jumping (11) despite the bone graft. Patients treated with bone graft reconstruction showed increased ankle dorsiflexion strength when compared to control subject who did not receive bone graft. There were no other objective differences in ankle strength and no difference in patient satisfaction scores. The authors concluded that the given additional operative time, postoperative weight-bearing restrictions, and potential for additional complications that reconstruction with bone graft may not be worth the cost.

Graft Insertion

Exposure of the recipient site should be carried out simultaneously with harvest of the fibula using two separate surgical teams. Appropriate bony resection and endplate exposure should be performed. The site of the anastomosis should also be exposed. The appropriate vessels should be isolated with vessel loops to maintain control. Several potential anastomosis sites are available for the placement of the fibula graft and depend on the location within the spine where the graft will be placed. Commonly used vessels include the external carotid artery and jugular vein (C1–C7),³⁴ superior thyroid artery (C3–C7),³⁵ the internal thoracic artery and vein (levels C7–T3),³⁶ the segmental renal artery and vein (T12–L1),³⁷ the lumbar segmental artery and retroperitoneal veins (L1–L5),³⁸ the iliac artery and vein (for anterior approaches to the lower lumbar levels and sacrum),³⁰ and the gluteal artery and vein (posterior approach to the lower lumbar levels and sacrum).³⁹ Multiple other anastomosis sites exist and can be used based on specific patient circumstances.

Generally speaking, it is advantageous to position the graft prior to performing the anastomosis to allow for better stability (Fig. 33.3). If there is enough length of the fibula, 1–2 mm section of the center of the bone can be removed (with care taken to preserve the vessels and soft tissues)

Fig. 33.3: Diagram of a vascularized fibula positioned in the cervical spine. Note the notches in the graft to minimize dislodgement. Vascular structures include (A) the peroneal artery and (B) the peroneal veins.

and the graft folded on its self to create a “double barrel” graft.³⁰ This allows for increased surface area and structural support. The graft may be trimmed as necessary to allow for placement; however, sufficient force should be necessary for graft placement to minimize the risk of later dislodgement. Care should be taken to make sure that the vascular pedicle is not compressed or torqued after insertion. If additional vessel length is needed for the anastomosis, the saphenous vein can be harvested and used as an interpositional graft.^{40,41} Once the anastomosis is complete any necessary instrumentation can be performed either at that time or from a secondary approach.

Postoperative Monitoring

Monitoring of an osteocutaneous flaps is relatively easy; the exposed skin can be evaluated for the presence of capillary refill and brisk bleeding from pin pricks to the skin. Evaluation of deep grafts is more difficult. Depending on the location of the anastomosis, a duplex ultrasound can be used; however, this is often difficult in spinal reconstruction due to the depth of the graft and the surrounding vessels that may interfere with the signal.⁴² Bone scintigraphy is the most commonly used tool for evaluating deep free bone grafts.^{43,44} Bone scintigraphs will generally become positive 7–14 days after surgery. Studies evaluating the use of bone scintigraphs in patients undergoing vascularized fibula graft for the treatment of avascular necrosis of the femoral head suggest that increased signal strength correlates with graft survival.⁴⁴ Dynamic enhanced MR imaging and single photon emission CT have also been shown to be valuable in the assessment of grafts placed for avascular necrosis.⁴⁵ While these imaging modalities are useful for predicting clinical outcome, they unfortunately are costly and time consuming and lack the ability to any regular, “real-time” monitoring of the graft that would allow for timely correction of any graft occlusion or venous congestion.

Clinical Results—Free Fibula Graft

The efficacy of free fibula grafts in the treatment of osteonecrosis of the hip and in reconstruction of the extremities has been well established.^{22,31,46–48} While there has been no larger study evaluating the use of vascularized fibula graft in spine surgery, many case reports and small clinical series have been published. A summary of these studies appears in Table 33.1. Most commonly, vascularized fibula grafts have been used for patients with

infections or with tumors, particularly those who have undergone preoperative or who will be undergoing postoperative radiation. Previous animal and human studies have demonstrated increased rates of pseudarthrosis in patients who have received radiation,^{49,50} with the highest incidence seen in patients receiving doses of 4,000 cGy or more. Moran et al. reported on a series of 12 patients who underwent free fibula bone grafting.⁵¹ Six of these grafts were performed purely for pathology occurring within the spine and the other 6 for combined spinopelvic defects. One patient died during the immediate postoperative period after an myocardial infarction (MI), and another had failure of his flap requiring a hemipelvectomy. Of the remaining 10 patients, 9 went onto fusion at an average of 4.5 months. The remaining patient required revision grafting but ultimately went onto fusion as well. In the series by Wuisman et al., 8 patients were treated with free fibula autograft, 4 of whom had tumors.²⁴ One patient died in the perioperative period from an unknown cause. All of the remaining 7 patients went onto fuse at an average of 4.5 months. Lee et al. published a series of 6 patients, 4 of whom were treated for tumors.³⁴ One patient died due to intraoperative hypotension and another whose graft failed due to thrombosis. This was revised with a second free fibula graft. Ultimately, all 5 surviving patients went onto fusion. A similar study by Ackerman on 7 patients (3 with tumors) showed fusion on 6 patients at an average of 3.2 months.³⁰

Many of the above studies also included patients who were treated for osteodisks/osteomyelitis. High rates of union were also seen in these patients. Erdman et al. specifically looked at the use of vascularized fibula grafts in patients who had infections and who had had previous spine surgery including anterior instrumentation.⁴¹ All four of the patients cleared their infection following surgery and a course of antibiotics. Three of the four went onto fusion without the need for any additional procedures. One patient, who was initially treated with anterior fibula grafting from L1 to L3 without instrumentation went onto nonunion at the cephalad level. This was treated with posterior fusion and instrumentation using iliac crest bone graft from T12 to L4. The patient subsequently went onto heal. Vascularized fibula grafts have been used to successfully treat infections in cervical spine as well.⁵⁵

Smaller cases reports and series have also looked at the effectiveness of vascularized fibula grafts in the treatment of deformity. Meyers et al. reported on pediatric patient with a grade 4 spondylolisthesis at the L5-S1

Table 33.1: Summary of case reports and case series of patients undergoing vascularized fibular autograft as an adjunct to spinal fusion surgery.

Author	Number of patients	Number of spine patients	Anatomic location	Pathology	Prior radiation	Mortality	Complications	Fusion rate	Mean time to fusion, mo	Mean length of follow-up, mo
Ackerman et al. ³⁰	7	7	Thoracic and lumbar	3 tumor, 4 osteomyelitis	Yes	0	1 graft failure—venous thrombosis	86%	3.2	38

level.³⁹ The patient had previously undergone resection of a neuroblastoma with radiation. The patient was initially treated with a nonvascularized fibula autograft but went onto nonunion and had progression of the slip and persistent neurological complaints. Revision surgery with a vascularized fibula graft passed posteriorly from S2 to L5 was performed. This resulted in fusion and no progression of the slip at 2 years. Freidberg et al. reported on the use of a vascularized fibula graft for progressive cervical kyphosis.⁵³ The patient was 24-year-old male who had previously undergone a posterior cervical laminectomy for the treatment of an Arnold-Chiari malformation. He subsequently developed progressive kyphosis and myelopathic symptoms and had an anterior fusion from C3 to C5 without correction of the kyphosis. His symptoms continued to progress. He ultimately underwent an anterior corpectomy removing all of C3, C4, and C5 and a fusion was performed using vascularized fibula graft from C2 to C6. The patient went onto fuse and had stabilization of his neurological symptoms.

Donor Site Complications

In addition to the risk associated with these intricate spinal procedures, the use of a vascularized fibular graft has the potential for complications at the donor site as well. In the immediate perioperative phase, these potential complications include poor wound healing, infection, iatrogenic nerve or vascular injury, and compartment syndrome. Tang et al. reported a 17% incidence of wound-healing problems including 4% that required a secondary procedure.⁵⁶ They also reported a 33% incidence of iatrogenic injury. Of these the majority were minor (defined as a neuroma or sensory defect), but there was a 2% incidence of major complication (fracture, paralysis or vascular injury). Long-term complaints include pain (11.5–60%), dysesthesia (11.8–50%), subjective instability (30–42%), an inability to run (20%), and objective weakness (10–37%).^{56–58} Weakness was most commonly reported with great toe extension followed by great toe flexion, although there have been reports of weakness in other toes and in the ankle. The weakness was often minor, commonly only slightly weaker than the contralateral side (4/5) and only occasionally having some weakness relative to gravity (3/5).⁵⁷ Vail et al. suggested that sensory and pain around the ankle complaints tended to increase over time following the surgery, while any motor weakness observed at 3 months following surgery was also seen at 5-year

follow-up.⁵⁷ Gait analysis have demonstrated decreased walking preferred velocity in patient undergoing vascularized fibula graft as well as increased variation in stride time while walking at increased velocity and with increased loads.⁵⁸ These finding suggest that the normal patterns of gait are not re-established following fibular autograft; however, the impact of these gait abnormalities to the patients in their activities of daily living is thought to be minor. Late fractures of the fibula graft have also been reported in patients undergoing vascularized fibula graft performed for the treatment of defects in the extremities.^{45,54}

When performing a vascularized fibula graft in skeletally immature children, there is an additional risk of developing a valgus deformity at the ankle due to asymmetric growth between the fibula and the tibia.⁵⁹ A tibiofibular syndesmosis performed at the time of index surgery minimized the risk of valgus deformity. Omakawa et al. also reported that, if the deformity is caught early a lateral wedge osteotomy can be performed to correct it.⁵⁹ This suggests the need for regular radiographic postoperative monitoring in children undergoing this procedure.

SUMMARY

The ability of vascularized grafts to achieve fusion in even the most challenging environments has been well documented; however, the advantages of these procedures must be balanced against the high level of surgical skill required to perform them, the increased operative time and the increased risk associated with these procedures. For the majority of cases, fusion can be achieved with conventional bone grafting techniques. However, for complex cases where a high likelihood of pseudarthrosis can be anticipated, the use of vascularized bone graft can be invaluable. Most commonly, these cases involve resection of tumors with concomitant radiation treatment, infections, especially after prior failed surgical treatment, or deformity. When possible, local transfer of vascularized rib graft may be adequate. The free transfer of a vascularized fibula may be more appropriate when increased structural support is needed or in areas of the spine where local transfer is not possible. The techniques for microvascular anastomosis used to perform a vascularized fibula graft are not familiar to most spine surgeons and team approach is recommended. While the indications for vascularized bone graft in spine surgery are limited, the use of these techniques can be invaluable in the treatment of complex spine pathology.

INTRODUCTION

Bone morphogenetic protein (BMP) has always remained a subject of excitement as well as controversy since 1965, when Marshall Urist¹ was able to demonstrate the osteogenic potential of demineralized bone pieces, when implanted into animals intramuscularly. He introduced the term “bone morphogenetic protein” for an active ingredient, which he postulated to be present in bone matrix, capable of differentiating pluripotent cells into osteogenic cells. Today BMP is the only unique bone growth factor known, which is capable of differentiating pluripotent cells into osteogenic cells. Thus, BMP is a mitogen as well as a morphogen.²

Reddi and Sampath later demonstrated that only the protein component of bone matrix was capable of inducing new bone formation.² Today several types of BMPs have been identified; however, FDA (Food and Drug Administration) approval has only been given for BMP-7 (OP-1, Stryker biologics, Hopkinton, MA) and BMP-2 (InFuse Bone graft, Medtronic, Memphis, TN) for human use. Urist used semipurified human BMP extract for his experiments, and one other bovine BMP extract called Ne-Osteo TM has been used in rats and nonhuman primates. Both commercial BMP preparations (BMP-2 and BMP-7) available for human use are produced through recombinant DNA synthesis technology and thus are free from risk of infection transmission or allergic reactions.²

BONE MORPHOGENETIC PROTEIN STRUCTURE

Bone morphogenetic protein belongs to the transforming growth factor-beta (TGF- β) super family, which also includes growth and differentiation factors, anti-Mullerian hormone, activin, nodal, and TGF- β s. Bone morphogenetic protein 1 is not part of this super family as it does not have the C-terminal of TGF- β . More than 47 members of BMP family have been discovered to date.²⁻³

Bone morphogenetic proteins can be divided into three groups based on their amino acid sequence. The first group contains BMP-2 and BMP-4. They differ mainly in the amino terminal sequence. The second group contains BMP-5, 6, 7 (OP-1), and 8 (OP-2). These molecules are relatively larger than the first group. The third group contains BMP-3 (osteogenin), which is quite different.^{4,5}

Human BMP comprises only 0.1% by weight of all bone protein and is most abundant in diaphyseal cortical bone. It exists in the extracellular matrix and is not accessible until the bone matrix has been demineralized.⁶ The basic structure of BMP (30–38 kDa) is in the form of two subunits, which can be identical (homodimer) or different (heterodimer). Heterodimers are difficult to prepare than homodimers, and currently available BMP preparations consists of homodimers only although heterodimeric formulation consisting of BMP2/BMP7 has been reported around 20 times more potent than homodimers.²

HOW BMP WORKS?

The hallmark of BMPs is their ability to enhance osteoinduction. The osteoinductive role of BMPs acts as both a chemotactic agent and a growth and differentiating factor.⁴ Bone morphogenetic protein is capable of stimulating the entire process of bone formation. However, Cheng et al. reported that BMP-2, 6, and 9 are more effective in inducing osteogenesis from differentiation of precursor cells than other BMPs.^{4,7}

Bone morphogenetic proteins can induce both endochondral and intramembranous bone formation depending upon its concentration, the carrier, site of implantation, and oxygen tension.^{2,8} Various cells, such as mesenchymal stem cells, osteoblasts, and osteoclasts, have specific receptors for BMP. There are two receptor types: BMPR I and II. Bone morphogenetic protein receptor I is further divided into types IA and IB. These different receptors are the reasons why different types and same types of cells with different ages respond differently to BMP.³

The binding of BMP to these receptors triggers a second messenger pathway in the cytoplasm leading to the expression of BMP response genes in the nucleus. A set of signal modulating proteins called Small “Mothers Against” Decapentaplegic (SMADs), which are present in the cytoplasm, further moderates the BMP gene transcription. This chain leads to cellular migration or chemotaxis, cellular proliferation, and their differentiation into chondrocytes or osteoblasts. Low concentration of BMP and less oxygen tension lead to endochondral bone formation, while high concentration of BMP and more oxygen tension stimulate direct intramembranous bone formation.² In addition to bone formation, BMPs have also been shown to impact the development of viscera, postnatal growth, and intervertebral disc homeostasis.^{3,8}

The bone formed as a result of BMP application is usually physiologically normal. Also, the osteoinduction and thus bone formation occur locally only without any systemic augmentation. This osteoinduction is limited temporally only to the time when the BMP is present. The action of BMP is controlled by many factors at many levels. Various soluble inhibitory proteins, such as noggin, chordin, and follistatin, inhibit the binding of BMP to receptors extracellularly. Intracellularly, the combination of signal transducing and inhibitory SMAD proteins controls the action of BMP as mentioned earlier.⁶

Fig. 34.1: Pharmacological bone morphogenetic protein (BMP) is first prepared in a solution form in a syringe and then sprinkled over collagen patches, which serve as a carrier for BMP.

PHYSIOLOGICAL VERSUS PHARMACOLOGICAL BMP

Bone morphogenetic protein is normally present physiologically in human bones in very small concentration and plays an active role in normal bone healing. To achieve a spinal fusion, a larger concentration of BMP is required to compensate for the diffusion of recombinant BMP from the site of application. Also, the degradation of pharmacologically applied BMP is rapid. There are some natural inhibitors of BMP in vivo like noggin and chordin, which attenuate the action of pharmacologically applied BMP.²

Pharmacological Recombinant Human (rhBMPs) are soluble factors and tend to diffuse away from the fusion site when used alone. Therefore, these factors are combined with a carrier that serves to contain the BMPs and release them gradually (Fig. 34.1). These carriers may also act as osteoconductive scaffolds.^{6,9} Various other carriers of rhBMP-2 include organic carriers such as polylactic acid polymer, collagen, demineralized bone matrix, autograft, and noncollagenous protein carriers, and inorganic carriers like hydroxyapatite-tricalcium phosphate (HA-TCP); true bone ceramic made from sintered bovine bone have been tested in various animal studies and have been found useful.^{2,10-12}

ROLE OF BMP IN LUMBAR FUSION

Spinal fusion is a commonly done procedure across the world to stabilize the spine for various disorders, since

Albee¹³ first described it in 1911. Approximately 250,000 bone graft procedures are performed each year for spinal fusion, and bone graft is the second most common human tissue to be transplanted. Associated donor site morbidity and the limited amount of bone graft have always led to the search for an ideal alternative. Allografts, bone substitutes, and growth factors have been used; however, each has its own merits and demerits.⁴

Various animal and human studies have shown that pharmacological application of BMP is an efficient mean to enhance or achieve spinal fusion. Most of the studies involve the use of rhBMP-2, while rhBMP-7 (OP-1, Stryker biologics, Hopkinton, MA) has recently been cleared for humanitarian device exemption “as an autograft alternative in compromised patients requiring revision posterolateral lumbar fusion, for which autologous bone and bone marrow harvest are not feasible or are not expected to promote fusion.”²

Boden et al. studied the role of rhBMP-2/HA-TCP in posterolateral lumbar fusion following laminectomy in nonhuman primates and found a dose-dependent increase in the amount as well as quality of bone with rhBMP-2.¹⁰ Bone morphogenetic protein has also been reported to surmount the negative effect of nonsteroidal anti-inflammatory drugs, chemotherapy, and nicotine in various studies.^{2,14-16} rhBMP-2 has even been shown to increase the volume as well as maturity of spinal fusion mass, when added to autograft.²

Boden et al.¹⁷ showed higher rates of new bone formation in the nonhuman primate model undergoing intertransverse fusion when rhBMP-2 was added to decorticated bone. Sandhu et al.¹⁸ reported that intertransverse fusion was obtained with rhBMP-2 without decortication.

In 2000, Boden et al.¹⁹ published the results of a prospective, randomized controlled, human clinical pilot trial to determine the feasibility of using rhBMP-2/collagen as a substitute for autogenous bone graft inside interbody fusion cages used in Anterior Lumbar Interbody Fusion (ALIF) surgery to achieve arthrodesis in humans. However, the sample size ($n = 14$) was very small. The arthrodesis was found to occur more reliably in patients treated with rhBMP-2-filled fusion cages than in controls treated with autogenous bone graft. There were no adverse events related to the rhBMP-2 treatment. Serology analysis did not show any increased BMP antibodies titer in patients treated with rhBMP-2. This study was one of the first to show consistent and unequivocal osteoinduction by recombinant growth factor in humans.

In 2002, Burkus et al.²⁰ published the results of a multicenter prospective, randomized, nonblinded, 2-year study involving 279 patients undergoing anterior lumbar interbody fusion for degenerative lumbar disc disease, and reported better fusion rates with rhBMP-2 as compared to autogenous iliac crest bone graft. There were more complications in the bone graft group. In 2002, the FDA approved the use of rhBMP-2 on an absorbable collagen sponge, when placed inside the fusion cage as an autograft substitute for anterior lumbar interbody fusion.^{2,8} However, various surgeons have used it for various off-label indications as well.

Alexander et al.²¹ used the rhBMP-2 with posterior lumbar interbody fusion and reported slower fusion rates in BMP group. They also found new bone formation along the insertion track of cages, however without any neurological deficit. In view of potential harmful effect, they stopped this study.^{4,21}

Boden et al.²² used a ceramic carrier instead of a collagen sponge and used a total of 20 mg rhBMP-2 per side (2.0 mg/mL concentration) for posterolateral fusion in humans and achieved 100% fusion rate for BMP-2 as compared to 40% fusion rate in autograft alone. Glassman et al.²³ conducted a prospective randomized nonblinded study of iliac crest bone graft versus rhBMP-2/compression-resistant ceramic matrix composite. They used a total of 40 mg rhBMP-2 (20 mg on each side) in a concentration of 2.0 mg/mL in 10 mL of ceramic matrix and found statistically higher fusion grades in rhBMP-2 group as compared to autograft at 6 months as well as 12 months follow-up.

In a recent report by Gerszten et al.,²⁴ clinical outcomes were similar for patients who underwent an AxiaLIF L5-S1 interbody fusion with or without rhBMP-2. Their data suggested that there is no statistically significant difference on fusion rates when using rhBMP-2.

Clinical results of rhBMP-7 are less promising as compared to rhBMP-2. Vaccaro et al.²⁵ conducted a prospective, randomized, controlled, multicenter clinical pilot study comparing the rhBMP-7 (OP-1) with autogenous iliac crest bone graft. They reported that rates of radiographic fusion, clinical improvement, and overall success associated with the use of OP-1 were at least comparable to that of the autograft controls for at least 48 months after surgery. They also suggested rhBMP-7 as a viable bone graft alternative for spinal fusion.

A recent published review of the Nationwide Inpatient Sample from 2002 to 2008 studied the impact of BMPs on frequency of revision surgery, use of autograft bone, and

total hospital charges in surgery for lumbar degenerative disease. The assessment found 46,452 patients from 2002 to 2008 undergoing thoracolumbar or lumbar arthrodesis procedures for degenerative disease. There was a steady growth in lumbar spine fusion and in the use of BMP. The use of BMP increased from 2002 to 2008. Revision procedures decreased over the study period. The use of autograft decreased substantially after the introduction of BMP but then returned to baseline levels; there was no net change in autograft use from 2002 to 2008. Use of BMP correlated with substantial increase in hospital charges.²⁶

Crandall et al.²⁷ published the results of a retrospective review of prospectively collected data of a large series. A total of 509 consecutive adults underwent open posterior instrumented fusion, augmented with Transforaminal Lumbar Interbody Fusion (TLIF) at 872 levels using a cage and rhBMP-2, with minimum 2-year follow-up. Cohort diagnoses included 179 degenerative, 207 spondylolisthesis, and 123 deformity patients. The efficacy of TLIF with BMP is supported in this large series with long-term follow-up, independent of industry. Reliable fusion and improved outcomes can be expected in adults undergoing TLIF for deformity, spondylolisthesis, and degenerative disease. Most complications occurred in patients with deformity.

CONCERNS WITH BMP USE

Although the FDA has approved BMP for some selected indications, spine surgeons have been commonly using them for off-label indications. Unfortunately, the off-label use of BMP is occurring more often than approved indications (Fig. 34.2). This has led to the emergence of various adverse effects associated with BMP use. Various commonly reported adverse effects when rhBMP-2 has been used in posterior lumbar interbody fusion include local bone resorption,²⁸⁻³⁰ postoperative radiculitis,³⁰⁻³³ endplate osteolysis with interbody device subsidence, and ectopic bone formation.^{34,35}

Various *in vitro* studies have suggested a notable host inflammatory response as the mechanism of action by which rhBMP-2 augments spine fusion.³⁴ As the pharmacological dose of rhBMP-2 is about 1 million fold more than the physiologic concentration, a possibility of potent local inflammatory response exists.^{34,36} Reported complications such as soft tissue swelling, hematoma formation, cyst formation, and vertebral body resorption demonstrate a host reaction associated with the use of rhBMP-2 in the spine.³⁴ Taher et al.³⁷ recently reported a serous contralateral psoas muscle fluid accumulation after BMP-2

Fig. 34.2: Off-label use of bone morphogenetic protein (BMP) is much more common than approved indications. In this case, BMP is used inside a banana cage for TLIF, which is not approved by FDA.

implantation for lateral lumbar interbody fusion. Merrick et al.³⁸ reported a case of “acute epidural lipedema,” rapid accumulation of edematous adipose tissue causing cauda equina syndrome after a lumbar decompression and fusion surgery using rhBMP-2. They also cited an intense inflammatory reaction as a reason for this.

Another potential complication inherent to BMP use has been the ectopic bone formation. Various factors,³⁴ such as position of the interbody cage in relation to the posterior margin of vertebral body,^{39,40} amount of BMP,^{33,41} carrier of BMP,³³ and the absence of a posterior barrier confining BMP to the interbody space³³ have been linked to ectopic bone formation. Mannion et al. used a relatively low dose of BMP with minimally invasive lumbar interbody fusion; however, they still reported the same complications.⁴²

Containment of rhBMP-2 and associated inflammatory reaction seems to be most important to limit the complications.³⁴ Intact posterior annulus and posterior longitudinal ligament appear to be protective of this reaction occurring in anterior lumbar interbody fusion surgery.⁴³ Posterior interbody techniques allow access of rhBMP-2 to the epidural space and neural elements as the posterior annulus is removed. Various barrier techniques have been described including the placement of one sponge against the anterior annulus followed by placement of local autograft or allograft behind the sponge, followed by the allograft strut, and completing the barrier with morselized cancellous allograft posterior to the strut.⁴⁴ The use of fibrin glue⁴⁵ has shown an effective method of limiting diffusion and ectopic bone formation.

Besides this, adequate hemostasis is essential to avoid the absorption of BMP by a hematoma at the decompression site. It is not advisable to leave collagen-based hemostatic agents, where decompression has been performed, in contact with the BMP implant, because BMP may elute from its collagen carrier into the collagenous hemostatic agent and thus enter the region of decompression. Leakage of rhBMP-2 or OP-1 outside the fusion area may lead to adjacent-level fusion.⁶

Even with on-label indication of BMP use for ALIF, several studies have reported higher rates of retrograde ejaculation (RE) with BMP use. This effect may be associated with an increased risk of postoperative urinary retention after BMP-2 exposure. The magnitude of the RE effect may be increased with concomitant prostatic disease treatments.⁴⁶⁻⁴⁸ Comer et al.⁴⁸ also suggested that RE rate may be decreased by careful handling of the BMP-2 around anterior spinal structures.

Carragee et al. reported eight new malignancies in the rhBMP-2 group and only two in the Iliac Crest Bone Graft (ICBG) group ($p = 0.1$) in a randomized controlled trial.^{49,50} Lad et al.⁵¹ reported the results of a large, independent, propensity-matched study ($n = 4,698$) and suggested that the use of BMP in lumbar fusions is associated with a significantly higher rate of benign neoplasms, but not malignancies.

Very recently, the YODA (Yale University Open Data Access Project) report was completed and published.⁵² They found that after a systematic evaluation and synthesis of all available evidence, both systematic reviews published independently concluded that rhBMP-2, compared with iliac crest bone grafting, does not improve pain or function and increases adverse events, possibly including cancer.

BONE MORPHOGENETIC PROTEIN IN INFECTION AND TUMORS

Although the use of rhBMP-2 in the presence of infection and tumor represents contraindications outlined by its manufacturers,⁵³ there have been published reports describing the use of BMP in these indications. Allen et al.⁵⁴ published a case series of 21 patients with vertebral osteomyelitis in whom they used rhBMP-2 in an off-label manner along with an anterior structural allograft or titanium cage and posterior instrumentation and fusion with iliac crest autograft.

FUTURE APPROACHES FOR BMP IN SPINAL FUSION

Many experimental approaches involving gene therapy are being investigated to expand the role of BMP in spinal fusion. These approaches involve the delivery of complementary DNA encoding BMP gene, using various vectors for BMP gene delivery, or in vitro transduction of cells with BMP gene, followed by implantation of these cells into the host. Postulated advantages of this gene therapy include more prolonged and physiological BMP production rather than a large single bolus pharmacological dose.²

A new protein called LIM mineralization protein-1 (LMP-1) has also been studied, which is an intracellular protein and is thought to induce osteoinduction. Osteoinductive properties of LMP-1 involve the synthesis of several BMPs and the recruitment of host cells that differentiate and participate in direct membranous bone formation.⁵⁵

Gene therapy has opened a new frontier for the role of BMP in spinal fusion; however, it is a double-edged sword and has potential risks in the form of neoplasms, infections, and immune responses to the viral vectors leading to immune reaction, toxicity, or organ failure. A continued and improved understanding of BMP in spinal fusion will help to circumvent these issues and will bring cost-effective as well as safe strategies to optimize the use of BMP in lumbar fusion.

Standard and Extended Transoral Approaches to the Upper Cervical Spine

Morio Matsumoto

Snapshot

- » Standard Transoral Approach
- » Extended Transoral Approach

- » Complications

INTRODUCTION

The craniovertebral junction (CVJ) and upper cervical spine are occasionally involved in cases of tumor, inflammatory disease (such as rheumatoid arthritis (RA) and pseudotumor), and congenital disease. Patients with clinical symptoms including pain and neurological deficits due to these diseases need decompression and fusion surgery, and those with locally aggressive tumors require tumor resection combined with reconstruction.

There are several possible surgical approaches to lesions in the CVJ and upper cervical spine including posterior, posterolateral, anterolateral, and anterior. Regardless of the approach, the complex anatomy of the upper cervical region, which includes the cranial nerves and carotid vessels, makes surgery of the CVJ and upper cervical spine technically demanding.

Of these approaches, the transoral anterior route is a very straightforward way to reach the CVJ and the upper cervical spine. This is largely because there are no critical anatomic structures, such as cranial nerves or carotid arteries, in the midline. Transoral approaches can be divided into standard and extended approaches. The standard approach is not accompanied by an osteotomy of the maxilla or mandible, while the extended approach requires an osteotomy of these structures to create a wider surgical field.

The transoral approach was first described by Kanavel¹ as the simplest and most commonly used approach for ventro-medial extradural lesions of the CVJ. It was

popularized by Fang et al.² for the treatment of atlantoaxial lesions such as dislocation and tuberculosis. Later, Menzes et al.^{3,4} and Crockard et al.^{5,6} separately reported successful anterior decompression of the upper cervical spine using this approach.

The extended approach has been used in the otorhynolaryngeal area for the resection of tumors in the pharynx and tongue.⁷⁻¹⁰ The first use of this approach for spinal surgery was reported by Hall et al.¹¹ for the treatment of myelopathy due to fixed cervical kyphosis in the upper cervical spine. This approach is frequently chosen for the treatment of primary malignant tumors in the upper cervical spine that require aggressive resection, including chordoma, giant cell tumor, and chondrosarcoma.¹²⁻¹⁸

STANDARD TRANSORAL APPROACH

Indications

This approach is indicated for lesions in the ventral upper cervical spine, including irreducible atlantoaxial subluxations when the odontoid peg compresses the medulla and spinal cord, rheumatoid pannus, pseudotumor, congenital anomalies with craniocervical settling, fixed atlantoaxial rotatory fixation, pyogenic spondylitis, tuberculosis, and intra- and extradural tumors.

Using this approach, the odontoid process can be resected, and the medulla and spinal cord can be decompressed.^{5,6,19} Pyogenic and tuberculous spondylitis at C1-2 can be debrided followed by anterior atlantoaxial arthro-

desis through this approach or by posterior occipitocervical fusion.²⁰ This approach is also used to biopsy lesions in the upper cervical spine.²¹ For primary malignant tumors such as a chordoma that requires total surgical resection, an extended approach is often necessary. In addition, for patients with limited oral opening, as is often seen in cases of RA, an osteotomy of the mandible and/or maxilla may be necessary.

Recent advances in posterior instrumentation surgery, including pedicle screws, transarticular screws, and lateral mass screws, have gradually obviated the need for the transoral approach. Rigid posterior instrumentation permits indirect decompression by reducing cranial settling²² and atlantoaxial subluxation. Spontaneously regressed pannus or pseudotumor can often be treated by the posterior approach alone as well.²³

Surgical Anatomy

The retropharyngeal wall is composed of the mucosa, buccopharyngeal fascia, constrictor muscles, prevertebral fascia, and prevertebral muscles (longus capitis and longus coli). The anterior longitudinal ligament covers the vertebrae. Usually, the anterior tubercle of C1 can be palpated easily from the mouth, at the midpoint.

The atlanto-occipital membrane connects the foramen magnum with the anterior arch of the atlas, and the apical ligament is attached to the apex of the odontoid process. The atlantoaxial joint can be reached bilaterally by retracting the flap of the mucosa, the prevertebral muscles, and the fascia laterally. The odontoid process can be found after the resection of the anterior arch of C1, and the transverse ligament lies behind the odontoid process.

Preoperative Preparation

Comprehensive radiographic work-up includes magnetic resonance imaging (MRI) and computed tomography (CT) scans. A CT angiogram of the cervical spine is recommended to look for abnormality of the vertebral arteries, which often occurs in patients with congenital anomalies and RA.

Hygiene of the oral cavity is important to prevent postoperative infection. Patients are encouraged to wash their mouth using a povidone-iodine solution. They should be referred to a dentist to check, if they have dental caries, which must be treated before surgery. Broad-spectrum antibiotics that will cover anaerobic bacteria should be administered prior to surgery.^{7,24}

For patients with tumors, pannus, pseudotumor, or with cranial settling of the odontoid process due to RA or a congenital anomaly, posterior stabilization with or without reduction of the basilar invagination should be performed

prior to the anterior procedure. Postoperatively, anesthesia must be consulted for postoperative respiratory management and otorhinolaryngologists should be asked to assess the retropharyngeal wound.

Surgical Technique

The patient is placed supine on the operating table. The skin is disinfected with povidone-iodine solution and the oral cavity with benzethonium chloride or chlorhexidine gluconate solution. Transoral intubation is conducted, and an endotracheal tube is placed. The authors prefer the RAE endotracheal tube, which goes underneath the tongue retractor, so it does not interfere with the surgical procedure. Alternatively, the tube can be placed at either corner of the mouth. If necessary, a central line is placed for hemodynamic monitoring during surgery and for postoperative total parenteral nutrition. To achieve good visualization of the retropharyngeal surgical field, the uvula and soft palate are lifted up using Nelaton's soft catheters, which are passed through the nostril on each side, pulled out through the mouth, and clipped using Kocher clamps under light tension.

After draping, a self-retaining oral retractor is placed and the mouth is kept open. The tongue retractor is attached and the tongue is pressed down to allow for a wide surgical view (Fig. 35.1A).²⁵ The retractor needs to be released every 30–40 minutes to prevent ischemia and congestion of the tongue. A stay suture is placed in the uvula, which is shifted away from the midline. If the lower end of the clivus needs to be visualized, the soft palate is divided at the midline.

The procedures used to increase the surgical field described below must be performed under good illumination, using a surgical microscope. More recently, transoral or transnasal endoscopy has been used for visualization of the occipitocervical junction, thereby minimizing surgical invasiveness and palate dissection.²⁶

After infiltration of 0.5–1% lidocaine and 1/1–200,000 epinephrine, the retropharyngeal wall (i.e. the mucosa and muscles) is incised at the midline using a knife. The anterior tubercle of C1 can be palpated and serves as a landmark for the incision. Caution should be used to accommodate for C1 rotation. Using electro cautery the prevertebral muscles, such as the longus colli and longus capitis, and the anterior longitudinal ligament are then divided and separated from C1 and C2. The mucosa and muscles are then retracted bilaterally using deep self-retaining Crockard retractors (Fig. 35.1B). Usually, this approach allows visualization of the tip of the odontoid process and the lower portion of the clivus cranially, the bilateral anterior atlantoaxial joints laterally, and the C2 vertebral body and the upper part of the C3 vertebral body caudally.²⁷

(B) After incision of the anterior longitudinal ligament and periosteum. A, lateral atlantoaxial joint; B, retropharyngeal mucosa and constrictor muscles; C, C2 vertebral body; D, anterior arch of C1; E, anterior atlanto-occipital membrane. *Source:* Reprinted with permission from Matsumoto M. Anterior decompression of upper cervical spine. In: Toyama Y (Ed). Integrated Handbook of Orthopaedics, Vol. 6. Nakayama Shoten Co, Ltd, Tokyo; 2009. pp. 114-18 (in Japanese).

The anterior arch of C1 can be easily resected using an air drill and Kerrison rongeur, which then permits visualization of the odontoid process. If the odontoid process is compressing the brain stem or spinal cord, it can be resected through this approach. Thereafter, any pannus and pseudo-tumor located behind the odontoid process can be resected in the same approach.

The bilateral anterior atlantoaxial joints also can be exposed after the dissection of periosteum and joint capsules laterally. Release of the joints in patients with irreducible atlantoaxial subluxation or fixed rotatory fixation can be performed using an air drill and Penfield dissectors. Care must be taken because lateral exposure of the atlantoaxial joints may endanger the vertebral arteries.²⁴

Anterior atlantoaxial arthrodesis can be performed by curettage of the anterior atlantoaxial joint cartilage and autologous bone graft, as described by Fang.²

Recently, some authors reported the use of an anterior screw and plate system to stabilize the atlantoaxial joint.²⁸

For the closure, each layer of the retropharyngeal mucosa and muscle is meticulously approximated, with absorbable 3-0 Vicryl sutures.

Postoperative Management

Patients are kept in the intensive care unit (ICU) on a ventilator overnight or for a couple of days, until the risk for airway obstruction due to retropharyngeal edema is reduced. The decision about when to extubate the patient

should be left up to the anesthesiologist. Oral feeding with clear fluid can be started several days after surgery, followed by soft food, if appropriate.

If a patient has atlantoaxial instability after the anterior procedure, posterior stabilization using instrumentation should be performed. If the posterior procedure is going to be staged, the patient should be placed in a Halo brace or kept in bed under traction while waiting for the surgery.

EXTENDED TRANSORAL APPROACH

The extended transoral approach can be accomplished by mandibulotomy (mandible-splitting), labiomandibuloglossotomy, and palatotomies. The addition of maxillotomy, including a Le Fort I osteotomy with or without palatotomy, allows for more vertical and axial extension of the surgical field, uncovering the whole clivus.⁸ Splitting of the soft palate is usually sufficient to visualize the lower end of the clivus, and tumors of the upper cervical spine can usually be resected without maxillotomy.

Youssef et al. conducted a cadaveric study in which they demonstrated the exposure achieved by using the transoral approach and its extended modifications.^{8,29} The standard transoral approach allows visualization of the clivus to the C2 body. A mandibulotomy visualizes the clivus to C3, and a labiomandibuloglossotomy visualizes the clivus to C4 and below.^{8,27,29} Surgeons should choose the surgical approach based on the extent of the tumor as demonstrated by preoperative MRI and CT.

Preoperative Preparation

Preoperative planning for the extended approach requires several additional preparations. Consultation with oral/maxillofacial surgeons and/or otorhinolaryngologists for help with mandible and tongue splitting and reconstruction is mandatory. Radiographic evaluation of the mandible including panoramic tomography should be performed.

Usually, extensive tumor resection at the upper cervical spine results in a loss of stability of the CVJ, and posterior occipitocervical fixation prior to the anterior approach is necessary. Finally, prior to surgery, tracheostomy should be conducted for intraoperative and postoperative respiratory control (Fig. 35.2A).

Surgical Approach

Preparation of the surgical field is the same as for the standard approach.

Mandible Splitting

Mandible splitting is usually conducted by oral maxillofacial surgeons. The lower lip is incised at the midline or it can be preserved and pressed down after the mandible is split. The authors prefer the latter for the isolated mandible splitting approach, because the cosmetic outcome is better.^{30,31}

The gingival and oral mucosa and the muscles attached to the mandible are stripped off, and the mandible is split in the midline between the central incisors using an oscillating saw and a chisel (Fig. 35.2B). The halves of the mandible are separated laterally using a spreader, and the tongue is depressed between them (Fig. 35.2C). Midline incision of the soft palate can be added to expose the lower portion of the clivus. This procedure allows for visualization of the retropharyngeal space from the clivus to C3 (Fig. 35.2D).

After incision of the retropharyngeal wall, a tumor at the upper cervical spine can be resected either en bloc or piecemeal. Successful en bloc resection of a chordoma was reported by Rhine et al.³² En bloc resection is technically very demanding because of the anatomy of the upper cervical spine, and piecemeal resection using a Cavitron ultrasonic surgical aspirator, airdrill, curettes, and rongeurs is more typical.

After the completion of tumor resection, anterior reconstruction between the clivus or C1 and C4 (or below) is performed using autologous iliac crest, fibula, or a titanium mesh cage.³³ The retropharyngeal wall is then meticulously closed in layers using absorbable 3-0 Vicryl sutures. If a

primary closure is not possible due to a large defect, the retropharyngeal wall should be reconstructed using a free or pedicle muscular flap. The two sides of the split mandible are then approximated using a titanium plate and screws by the oral surgeons (Fig. 35.2E).

An illustrative case of a patient with a C2 giant cell tumor treated by the extended transoral approach is illustrated in Figures 35.3 to 35.5. The patient is a 24-year-old female with progressive quadriparesis secondary to a giant cell tumor. She underwent a staged procedure to resect the tumor and stabilize her spine. One month later, the autologous iliac crest strut became dislodged. She underwent an additional surgery, and at 5-year follow-up, she was disease free and solid bony fusion had been obtained.

Mandibuloglossotomy

A mandibuloglossotomy requires elongation of the labium incision to the submental area. Following mandible splitting, the tongue is incised at the midline using electric cautery to preserve the nerves and vessels supplying the tongue. Figures 35.6 and 35.7 depict an illustrative case of a 62-year-old female patient with a recurrent chordoma at C2. The entire floor of the mouth was divided at the midline using a sharp scalpel (Figs. 35.7A and B). After meticulous hemostasis, self-retaining retractors were placed to separate the split halves of the mandible and tongue away from the midline while pushing the soft hypoglossal tissues down (Fig. 35.7C). In this case, the lower cervical spine needed to be visualized, so the incision was extended caudally along the sternocleidomastoid muscle (Fig. 35.7D). Alternatively, DeMonte et al. reported a circumglossal approach instead of the midline approach,³⁴ and Neo et al. reported the successful resection of a chordoma at C1 using a navigation system.³⁵

After the tumor resection is complete, the retropharyngeal wall is repaired as described above, and the tongue is sutured meticulously by oral surgeons or otorhinolaryngologists. Interestingly, dysfunction of the tongue after this procedure has been reported to be rare.

Postoperative Course

These patients require extended ICU stays until their respiratory condition can be stabilized. Total parenteral nutrition or tube feeding needs to be continued for several weeks until the patient can swallow without difficulty. Therapy for dysphasia should be actively conducted, and the condition of the retropharyngeal wall and swallowing function should be evaluated before the start of oral feeding.

(B) Radiograph at final, 5-year follow-up. (C) T2-weighted magnetic resonance imaging at the final follow-up demonstrating no recurrence.

COMPLICATIONS

The transoral approach, especially an extended one, is frequently associated with complications such as prolonged dysphagia and/or hoarseness, infection, dehiscence of the

retropharyngeal wall, leakage of cerebrospinal fluid, meningitis, dislodgement of graft, and occlusal disharmony. The risk of these complications may be higher in patients who have undergone radiation therapy. Matsumoto et al. reported significant complications in three patients follow-

Figs. 35.6A and B: Preoperative Gd-enhanced magnetic resonance imaging for a 62-year-old female patient with recurrent chordoma at C2.

Figs. 35.7A to D: Intraoperative photographs for the same patient as in Figure 35.6. (A) Labium and mandible were divided in the midline. (B) Tongue was divided at the midline using an electric cautery. (C) After placement of the retractors, the retropharyngeal space was easily examined visually. (D) An autologous fibula strut placed from the clivus to C4 after tumor resection.

ing the extended transoral approach who were previously radiated.³⁶

Several steps can be taken to reduce the risk of complications. Meticulous repair of the retropharyngeal wall by primary sutures or primary muscle flaps is essential. Pre- and postoperative use of wide-spectrum antibiotics is also important to prevent infection. Fine suture of the dura in cases of incidental dural tear or durotomy for intradural tumors is indispensable to prevent cerebrospinal fluid leakage and subsequent meningitis. Subarachnoid drainage should be considered, if tight closure of the dura is not possible. Aggressive postoperative swallowing training should be encouraged to prevent prolonged dysphagia. Finally, dislodgement of a graft or cage can pose a significant problem (*see* Fig. 35.5A). The graft bed should be meticulously prepared, and the CVJ should be stabilized by the placement of rigid posterior instrumentation.

KEY POINTS

- The transoral anterior approach is a very straightforward way to reach the CVJ and the upper cervical spine. There are no critical anatomic structures, such as cranial nerves or carotid arteries, in the midline.
- The standard transoral approach is indicated for lesions in the ventral upper cervical spine including irreducible atlantoaxial subluxation, RA-associated pannus, pseudotumor, congenital anomaly with craniocervical settling, fixed atlantoaxial rotatory fixation, pyogenic spondylitis, tuberculosis, and intra- and extradural tumors with limited extension.
- The extended transoral approach is performed with an osteotomy of the mandible and/or maxilla followed by glossotomy, if necessary.
- The extended transoral approach is indicated for malignant or aggressive tumors at the craniocervical junction

that require total resection, including chordoma, giant cell tumor, and chondrosarcoma.

- The extended transoral approach should be carried out by multidisciplinary surgical teams.

INTRODUCTION

The anterior approach to the cervical spine is an extremely practical and elegant approach to surgically address pathologies that arise primarily from the anterior spinal column.¹ The approach chosen depends on a number of factors, including the target spinal segments requiring exposure, the nature of the procedure to be performed, anatomical considerations including deformity, and the patient's body habitus. Additionally, anterior cervical approaches can complement posterior approaches to allow surgeons to achieve circumferential surgical objectives without compromise.

HISTORY

The anterior approach to the cervical spine was described as early as the nineteenth century.² At the beginning of the last century, surgeons were mainly involved with the treatment of complications of Pott's disease, namely deformity and drainage of abscesses, and later with management of neoplastic invasion and iatrogenic instability of the cervical spine after laminectomy procedures.³ As early as 1917, Henderson argued that posterior fusion was an ineffective procedure for cervical spine tuberculosis because it did not directly address the diseased anatomy.⁴ The need for more effective treatment options for Pott's disease of the cervical spine prompted

surgeons to investigate various anterior approaches to the cervical spine over the ensuing decades.⁵⁻⁸ In one of the earliest descriptions of modern anterior cervical fusion, Bailey and Badgely note that LC Abbot described the first use of an anterior cervical fusion for a lytic lesion of C4 and C5.⁹ Advances in anesthetic techniques, the ease of the approach, and its effectiveness in managing cervical spine lesions including fractures, neoplasms, and infections led to a rapid increase in the popularity of the anterior cervical surgical approach. The technique was extended to cervical degenerative disc disease by Robinson and Smith and Cloward, who first utilized the approach for interbody fusion.¹⁰⁻¹² In 1956, Hodgson and Stock concluded: "the anterior approach to the spinal column is a practicable proposition at all levels and is the only approach that allows accurate visual assessment of the extent of the disease."⁶

Crowe and Williams first utilized a transoral approach to remove an osteoma in 1944 and a similar approach was used in 1962 by Fang and Ong to treat six patients with traumatic C1-2 instability^{13,14} (Figs. 36.1 and 36.2). Henry in 1957 described a presternocleidomastoid approach to obtain surgical access to the vertebral artery and transverse apophyses, intertransverse foramina, and nerve roots up to the cervico-occipital region.¹⁵ This approach to the upper cervical spine was also later described and refined by Whitesides and Kelly in 1966.¹⁶ Anterolateral approaches (the high presternocleidomastoid approach,

retropharyngeal, and precarotid) were first described by Smith and Robinson in 1958.¹² Cloward described a similar approach later that year.¹¹ Similar later reports were made by de Andrade and Macnab in 1969 and Riley in 1973.^{17,18}

ANATOMY AND LANDMARKS

A thorough understanding of applied surgical anatomy and superficial landmarks that guide placement of incisions is vital for surgeons utilizing anterior surgical approaches to the cervical spine. The specific surgical anatomy of individual approaches is discussed later in the chapter. Palpable surface landmarks guide the placement of incisions,

as they generally overlie specific vertebrae or disc spaces. These include the hyoid bone (C3 level), thyroid cartilage (C4-5 level), carotid tubercle (C6 level), and cricoid cartilage (C7 level) (Fig. 36.3). Some caution should be used as deep palpation of the carotid tubercle could elicit an intra-operative vasovagal response.

ANTEROLATERAL APPROACH (SMITH-ROBINSON)

Preoperative Considerations

The anterolateral approach to the cervical spine is a utilitarian approach that allows access from C2 to T1 in most patients. Many procedures can be accomplished through this approach, including anterior decompression of the spinal canal (discectomy, corpectomy, epidural abscess evacuation, ventral tumors), anterior cervical fusion (for fracture, deformity, tumors, infection or degenerative processes), biopsy of the vertebral body or disc space and placement of anterior cervical instrumentation.

Certain anatomic considerations may limit the extent of the exposure achieved through this approach. The ability to access the C2-3 disc space depends on the position of the mandible. This can easily be assessed preoperatively on a lateral radiograph. Access to the C7-T1 disc space can be limited by the anatomic position of the manubrium. This again can be assessed on a preoperative lateral radiograph or midsagittal CT imaging. Often, special request to the CT imaging center is required to have the manubrium visualized simultaneously with the sagittal cervical spine images.

Fig. 36.1: Lateral view of the transoral approach. Diagram view. Include neck in hyperextension and mouth wide open. Include retractor with blade to depress tongue in image.

Fig. 36.2: Deep surgical dissection for transoral surgical approach.

Fig. 36.3: Diagram including side-by-side images showing hyoid bone (C3 level), thyroid cartilage (C4-5 level), carotid tubercle (C6 level), and cricoid cartilage (C7 level).

The patient is placed supine on a regular operating room table with the head in a neutral position or with the neck slightly extended and rotated away from the planned surgical incision. A roll or inflatable bolster beneath the scapulae can be used to facilitate neck extension. The head of the bed can be elevated to 30° to reduce intraoperative venous bleeding. However, it should be noted that placing the patient in reverse Trendelenburg can make it more difficult to visualize the disc in the subaxial spine secondary to its lordotic position. If neurological symptoms are noted with awake extension, an awake or neck-neutral fiberoptic intubation should be considered. The arms are placed at the patients' side, and the shoulders are typically depressed using tape attached to the foot of the bed to improve lateral radiographic visualization of the inferior cervical levels. Caution should be used as

taping the shoulders too aggressively can lead to changes in neurological monitoring secondary to traction on the brachial plexus. Intraoperative traction with Gardner-Wells tongs or Mayfield clamps is rarely necessary except in cases where deformity correction is required¹ (Fig. 36.4).

Incision and Superficial Dissection

Either a transverse or longitudinal/oblique skin incision is made centered over the level(s) of interest as determined by both landmarks and intraoperative fluoroscopy. Transverse incisions are made along Langer's lines, making them more cosmetic, but not as extensible. Extension of the incision past the midline can be useful as it eases soft tissue release. An oblique incision made along the medial border of the sternocleidomastoid has the benefit of being

Fig. 36.4: Image depicting positioning for Smith-Robinson approach. Should include head rotated to right, head of bed up 30°, small rolled up towels behind neck to facilitate extension, shoulders taped to bottom of bed.

more extensible, although less cosmetically appealing (Fig. 36.5). A “J”-shaped incision that combines a transverse incision with an oblique incision can also be used. Superficial surgical dissection begins by identifying the platysma. The fibers of the platysma are divided and the muscle is elevated superiorly and inferiorly. Releasing the subcutaneous fascia off of the platysma is useful to allow the skin opening to be more mobile, thereby making a small incision more extensible. The anterior border of the sternocleidomastoid muscle is identified next, and the deep cervical fascia immediately anterior to the muscle is divided (Fig. 36.6).

Deep Dissection

After palpation of the carotid artery, the pretracheal fascia immediately anterior to the carotid sheath is divided. Division of the pretracheal fascia should be performed just past midline taking caution to avoid the midjugular veins. The pretracheal fascia should be released off of the underlying structures and adequately mobilized. Blunt dissection is used to retract both the sternocleidomastoid and carotid sheath laterally and the sternohyoid, sternothyroid, trachea, and esophagus medially (Fig. 36.7). It is at this point that the obliquely crossing omohyoid is encountered. The omohyoid most commonly crosses the surgical field at the C5/C6 level. It can be identified, mobilized and retracted, or divided intrasubstance after confirmed isolation without sequelae. Typically,

Fig. 36.5: Transverse and/or longitudinal skin incision.

visualization of a multilevel anterior procedure is aided by omohyoid division. Blunt dissection is then used to develop a plane directly down to the anterior surface of the cervical vertebrae, being careful to coagulate or ligate all bleeding vessels to ensure a clear operative field. Care is taken to ensure an adequate longitudinal and lateral release to allow clear visualization and adequate mobilization and protection of the trachea and esophagus together with the recurrent laryngeal nerve (RLN).¹ The prevertebral fascia is bluntly swept off of the anterior longitudinal ligament (ALL) and paired longus colli muscle using a Kittner dissector and peanut. Verification of operative level is traditionally achieved with a double bent spinal needle in the disc space or a tonsil snap clipped to the ALL.

ANATOMIC CONSIDERATIONS AS RELATED TO COMPLICATIONS

Recurrent Laryngeal Nerve

The right RLN branches from the vagus nerve at the level of T1-T2 or inferior. After looping around the subclavian artery, the right RLN becomes invested in the tracheoesophageal fascia inferior to C7-T1. The right RLN travels superiorly, slightly anterior to the tracheoesophageal groove, before coursing between the trachea and the thyroid. After looping around the aortic arch, the left RLN is invested in the tracheoesophageal fascia inferior to the T2 level. The nerve travels slightly anterior to the tracheoesophageal groove and within the tracheoesophageal fascia before coursing between the trachea and thyroid, entering the larynx at

Fig. 36.6: Superficial dissection is identifying platysma, exposing sternocleidomastoid, and deep cervical fascia.

or inferior to C6-7. From an anatomic perspective, there is no appreciable side-to-side difference that could place either nerve under greater risk for injury based on side of approach, nor is there clinically a demonstrated increased rate of palsy based on side of approach.¹⁹ Injury to the RLN is typically a result of traction and pressure, which emphasizes the importance of mobilization. Electrophysiologic monitoring of the RLN has recently been used

to try to reduce injury to the nerve. In patients who have had prior anterior cervical surgery and require revision surgery, preoperative direct laryngoscopy for vocal cord evaluation should be performed if the revision procedure is going to be approached through virgin tissue. Palsy of the nerve requires an approach through the prior incision as damaging the contralateral nerve could potentially lead to palsy of both vocal cords.

Fig. 36.7: Deep dissection to the anterior cervical vertebrae.

Superior Laryngeal Nerve

The superior laryngeal nerve is found at the C3-4 level and transversely crosses the surgical field travelling with the superior thyroid artery. Injury to this nerve is infrequent, but results in high note phonation and decreased pharyngeal sensation, which can result in pharyngeal phase dysphagia and decreased pharyngeal.

Sympathetic Chain

The sympathetic chain is found on top of longus colli at lower cervical level from C6 and inferiorly. The surgeon should avoid dissecting on top of the longus colli as injury to the sympathetic chain can result in an ipsilateral Horner's syndrome. In addition, cervical retractors should be placed underneath the longus colli muscles and not allowed to migrate anteriorly over the surface of the muscles.

LATERAL RETROPHARYNGEAL (WHITESIDES)

Preoperative Considerations

Whitesides originally described the lateral retropharyngeal approach to the upper cervical spine in 1966 and refined it in 1978.²⁰ The approach was inspired by the work of Henry for exposing the vertebral artery throughout its cervical extent.¹⁵ This approach can be used for anterior access to the upper cervical spine but not the occiput. It is often used for high cervical bony lesions including tumors or infections for which a posterior approach is

not possible. It allows unilateral access to C1 through C3; access to the contralateral side requires a second approach. Unfortunately, this approach may not provide adequate access for anterior decompression or anterior strut grafting.²¹ The advantage of this approach is that it precludes contamination of bone graft from the nasopharyngeal bacterial flora that is inherent with a transoral approach to the high cervical spine.^{22,23}

The patient is placed supine on a regular^{22,23} operating room table with the head in a neutral position or with the neck slightly extended and rotated away from the planned surgical incision. The patient may be placed in halo traction and the approach still accomplished, albeit with difficulty, if instability is present. Nasotracheal intubation opposite the side of surgical incision is preferable. The pinna of the ear on the side of exposure can be sewn anteriorly to improve exposure.

Incision and Superficial Dissection

A longitudinal incision is made along the anterior margin of the sternocleidomastoid muscle. At its superior end, the incision can be carried posteriorly across the base of the temporal bone, and the sternocleidomastoid muscle can be divided at its mastoid origin.¹⁶ The incision can be extended as far as the sternal notch depending on the amount of required distal cervical spine exposure. The subcutaneous tissues and platysma are divided using electrocautery. Blunt dissection is carried out in the subplatysmal plane allowing creation of musculocutaneous flaps. The greater auricular nerve is next dissected out to allow

Fig. 36.8: Superficial surgical dissection for lateral retropharyngeal approach.

adequate retraction in a cephalad direction. If it is in the way, it may be resected with a negligible sensory deficit.

The sternocleidomastoid muscle is then everted and the spinal accessory nerve identified as it is approached and passed into the muscle. The accompanying vascular structures are divided and ligated. The sternocleidomastoid muscle is now mobilized and is retracted medially and anteriorly with the carotid sheath. With anterior approaches, the surgeon must dissect the branches of the external carotid artery and laryngeal nerves, retracting the carotid sheath posteriorly. The lateral approach avoids these structures, dissecting posterior to the carotid sheath and retracting it anteriorly (Fig. 36.8).

Deep Dissection

The lateral process of C1 and transverse processes of C2 and C3 are now palpable in the approach. Further dissection along the anterior aspect of the transverse processes and division of Sharpy's fibers allows exposure of the cervical vertebrae. The retropharyngeal space can be opened further with blunt dissection techniques. A sharp elevator or bipolar electrocautery can be used to elevate the longus capitis and longus colli muscles from the transverse processes and lateral masses. Localization is easy because of the prominent, transversely oriented anterior arch of C1 and the prominent vertical midline ridge of the base of the odontoid and body of C2. At the conclusion of the procedure, the sternocleidomastoid is sewn back into place over suction drains. The platysma and skin are closed in layers.

COMPLICATIONS

Adverse events occur infrequently, but several have been described, including esophageal injury, vertebral artery injury, dural tear, postoperative airway compromise, spinal cord injury, hematoma, dysphagia, dysphonia, and graft dislodgement.²⁴ These can be divided into three main categories based on when they typically occur: intraoperative, early (within one week), and intermediate (1–6 weeks).

Intraoperative complications include esophageal injury (0.2–0.4%),^{25–27} vertebral artery injury (0.3%),²⁸ dural tear (3.7%),²⁹ spinal cord injury (0.2–0.9%),^{26,29,30} or peripheral nerve injury (0.2–3.2%).^{24,26,27,31}

Early postoperative complications (within 1 week) include airway compromise due to edema or hematoma,^{29,32,33} epidural hematoma,^{26,27,29} or radiculopathy.^{26,27,31} Intermediate to long-term complications (1–6 weeks postoperatively) include dysphagia,^{34–39} dysphonia,^{34,40–42} or infection.^{26,27} Appropriate strategies must be utilized to avoid these adverse events, and the treating surgeon should have an understanding of how to detect and manage such events when they do arise.²⁴

SUMMARY

Anterior approaches to the cervical spine were developed for dealing with pathologies that arise primarily from the anterior spinal column. The approach chosen depends on a number of factors, including the target spinal segments requiring exposure, the nature of the procedure to be performed, anatomical considerations including deformity, and the patient's body habitus. Additionally,

anterior cervical approaches can complement posterior approaches to allow surgeons to achieve surgical objectives without compromise.

KEY POINTS⁵

- The anterolateral approach is the technique used to surgically address all anterior pathology in the subaxial cervical spine.
- The most common complication of an anterolateral approach in transient dysphagia.
- There is no difference in incidence of RLN injury between right and left sided approach.
- The Whitesides approach yields limited visualization for anterior decompression and strut grafting but eliminates nasopharyngeal contamination of surgical field.

Anterior Approaches to the Cervicothoracic Junction

Adewale Adeniran, Adam M Pearson

Snapshot

- » Preoperative Planning
- » Superficial Approaches
- » Deep Dissection

INTRODUCTION

The cervicothoracic (CT) junction generally refers to the region from C7 to T5, and the unique anatomic features of the CT junction make anterior exposures very difficult. The commonly used Smith-Robinson anterior approach to the cervical spine is frequently inadequate due to the kyphosis of the thoracic spine and the presence of the sternum that prevents one from accessing the anterior aspect of the vertebral bodies. With a direct anterior approach, one encounters the great vessels and important visceral organs. Lateral approaches via a thoracotomy that are typically performed for approaches to the lower thoracic spine maintain the disadvantages of navigating the visceral organs, while the presence of the scapula and other elements of the shoulder girdle including the brachial plexus limit its usefulness for the CT junction. Fortunately, one rarely needs to access this region anteriorly. Trauma, degenerative conditions, and most deformities can be safely managed with posterior only surgery at the CT junction. The original anterior approach was described by Cauchoix and Binet in 1957 in a classic talk given to the French Academy of Surgery on anterior approaches to the spine.¹ The authors note that the CT elements “have an unhappy reputation for depth and surgical inaccessibility.” They advocated extending a cervical approach inferiorly by using a median sternotomy, and described this approach in a patient with an invasive tumor and spinal cord injury. The exposure was limited caudally to T3, over which the arch of the aorta

was encountered. This extensile approach is extremely morbid and may not be necessary for most procedures at the anterior CT junction, although some authors persist in using it in the setting of deformity correction.² A multitude of less invasive approaches to this important area have been described, yet there remains room for innovation.

PREOPERATIVE PLANNING

The almost straightforward approach to the upper CT junction is the familiar Smith-Robinson anterior cervical approach between the carotid sheath laterally and the esophagus and trachea medially, with its inferior extent limited by the sternum and clavicle. Some upper thoracic or CT procedures can be performed safely without any additional exposure than that afforded by the anterior cervical approach. Unfortunately, there is tremendous variation in patient body habitus and degree of thoracic kyphosis, so the surface anatomy does not consistently correlate with a thoracic level in this region. Obtaining and interpreting orthogonal radiographs prior to surgery is crucial to a successful outcome, and radiographic methods of determining the need for an extended approach have been developed.³⁻⁶ Fraser et al., correlating magnetic resonance imaging landmarks with expert opinion on the feasibility of surgical approach, described a measure called the “instrument manubrial thoracic distance” which correlated best with surgeon opinion on the feasibility of a supraclavicular approach. Their method has been deemed

cumbersome by multiple authors.^{3,4} Karikari et al. have reported their results with a very simple method of determining the lowest accessible level. They define the lowest accessible disc space as that in which a straight line passing through and parallel to the disc space also passes above the manubrium. They consider that screws can be safely placed in the vertebral body immediately below this disc space. In their report of 12 surgical patients, the operative plan never needed to be changed including in two patients with body mass index > 35 and 4 cases where T3 was the lowest instrumented vertebra. Their subsequent review of 50 normal radiographs suggested that the C7-T1 level is accessible from the standard cervical approach in >90% of patients. Cho et al. measured a similar line on lateral plain films in 99 patients and successfully completed the supraclavicular approach in all 99 without need to change their operative plan.⁴ T1 was the lowest instrumented level in 85% of patients in this series, but one patient did have instrumentation to T3. There are no reports about attempting surgery to levels inferior to this line without an extensile approach, so it seems unlikely that this can be done in most patients. Additionally, the CT junction can be difficult to visualize on plain radiographs, so sometimes computed tomography can be a more useful study to determine the feasibility of an anterior approach to this region. Since the typical sagittal computed tomography scan of the cervical spine does not include the manubrium, a special computed tomography scan specifically asking for the manubrium to be included on the sagittal views may be necessary.

As the majority of procedures require access to the midline of the spine, the CT junction can be approached from either the right or left side. There is no evidence of superiority of either side, although a left-sided approach confers a theoretically increased risk of damage to the thoracic duct, while a right-sided approach theoretically places the recurrent laryngeal nerve at risk.

SUPERFICIAL APPROACHES

Median Sternotomy

The classic extensile approach is typically done with direct assistance or immediate availability of a cardiothoracic surgeon. It begins with the Smith-Robinson approach to the cervical spine, along the medial border of the sternocleidomastoid muscle, which is retracted laterally along with the carotid sheath. This incision is then joined with a midline incision over the sternum by dividing the

Fig. 37.1: The vertebrae from C4-T4 can be seen between the innominate artery and the aorta.

subhyoid musculature. The sternal incision is carried subperiosteally, and blunt dissection is used to mobilize the retrosternal soft tissues. The sternum is split longitudinally with a saw or osteotomes and retracted widely (Fig. 37.1).^{1,2} Closure is achieved with heavy gauge wires to reapproximate the sternum. Darling et al. modified this exposure by leaving the inferior portion of the sternum intact, dividing the sternum in the midline only to the level of the second intercostal space, before carrying their osteotomy laterally through the synostosis between the manubrium and the body of the sternum.⁷ They report excellent exposure down to the T3 level with this more limited exposure. Nazzaro et al. report an extension of this exposure, in which the incision is curved laterally along the fourth interspace to the midaxillary line.⁸ The internal mammary artery and vein are ligated and the interspace is opened by splitting the fibers of the intercostals. The lung on the operative side is deflated and the arch of the aorta as well as all the great vessels are mobilized inferiorly and controlled with vessel loops. This exposure allows access to lesions that are laterally as well as anteriorly based.

Clavicle Osteotomy

The clavicle osteotomy was developed in order to reduce the morbidity associated with sternotomy yet still allow easy access to the great vessels and provide a viable strut graft. As with a sternotomy, the anterior cervical exposure is carried out initially. The manubrial and sternal heads of the sternocleidomastoid muscle are then elevated from

Fig. 37.2: The clavicle and lateral manubrium has been elevated on a muscle pedicle.

their distal attachments and retracted. The medial third of the clavicle is then stripped of its periosteum as is the manubrium on the operative side. The medial clavicle is disarticulated from the manubrium and resected at the junction of the medial and middle thirds and saved to be used as bone graft. The manubrium can either be excised on the operative side or left intact as needed. If additional exposure or graft is needed, the incision can be turned into a T at the level of the sternal notch to allow osteotomy of both clavicles. Other authors maintain the sternoclavicular joint, elevating the lateral manubrium and the medial clavicle on a pedicle of sternocleidomastoid muscle and repairing the construct at the end of the case (Fig. 37.2).⁹ Exposure to the level of T3 has been described using these approaches.¹⁰

Sternal Osteotomy

Attempting to preserve the clavicles, sternoclavicular joints, and sternal body, Pointillart et al. developed a less invasive approach to the midline of the CT junction.⁶ Similar to the other extensile approaches, the standard anterior cervical approach is first undertaken. The sternal origins of the sternocleidomastoid and the infrahyoid muscles are released from their sternal border. A midline incision centered over the manubrium was then carried out to the periosteum, staying medial to the sternoclavicular joints and cranial to the sternal body. Finger dissection was used

to mobilize the retrosternal space, and a high speed burr was then used to thin the posterior cortex of the manubrium. A partial manubrial resection was then completed with Kerrison rongeurs. A long thin retractor then allowed access to the vertebral bodies without need for dissection of the great vessels. This approach typically allows access only down to T2.

DEEP DISSECTION

After initial choice of approach as described above, the surgeon must contend with limitations posed by the internal contents of the chest cavity. Most of the approaches detailed above allow easy access down to the T3 level after blunt dissection through the retrosternal fascia to the level of the vessels, but further caudal extension can be limited. Three predominant corridors have been developed to allow access down to T5.¹¹

Superior Corridor

The superior corridor is the traditional corridor and exists between the esophagus and trachea medially and the left common carotid or brachiocephalic artery laterally. The inferior extent of this corridor is the left brachiocephalic vein, which crosses the field about T3 or T4. Cauchiox et al. suggested ligating this vessel to obtain exposure, but this is rarely necessary as it can be safely retracted in most cases.¹ Excessive superior and inferior retraction in this corridor puts the superior laryngeal and recurrent laryngeal nerves at risk respectively. The sympathetic trunk lies between the posterior sheath of the carotid and the fascia of the longus colli and must be protected with a handheld blunt retractor (Fig. 37.3).

Middle Corridor

The middle corridor lies between the right brachiocephalic vein and artery and is exposed by retracting the right brachiocephalic vein to the patient's right. This must be done carefully as venous rupture has been described and can be catastrophic. The inferior limitation of this corridor is the confluence of the left and right brachiocephalic veins, which usually occurs at the T4 level¹¹ (Fig. 37.3).

Inferior Corridor

The inferior corridor allows exposure to T5 and is bordered by the superior vena cava on the right, the ascending aorta on the left, the left brachiocephalic vein superiorly, and

Fig. 37.3: The innominate (brachiocephalic) artery, veins, and tributaries.

the right pulmonary artery inferiorly. The tracheal bifurcation most commonly lies about the body of T4 and may act as an inferior restraint as well (Fig. 37.3).¹¹

CONCLUSION

Anterior approaches to the CT junction are technically challenging and are associated with high levels of morbidity. When possible, a posterior approach is favored. In cases in which oncologic principles of wide resection are being followed or if anterior column support is required and cannot be accomplished from a posterior approach, these approaches can provide access to this challenging region of the spine. Obtaining the assistance of a cardiothoracic surgeon is recommended for those unfamiliar with these approaches.

Evaluation and Treatment of Axial Neck Pain

Jesse L Even, James D Kang

Snapshot

- » Case Examples

INTRODUCTION

Neck pain is a very common complaint that is frequently encountered in primary care and spine clinics. Most people can expect to have episodes of neck pain during their lifetime, but a majority will not have neck pain that interferes with normal activities. Diagnosing and treating the cause of axial neck pain can be difficult, and even when there is a clear diagnosis for the symptomology, often times, there is no intervention that can predictably cure the cause of pain. The goal of this chapter is to define the etiology of axial neck pain and review the appropriate evaluation (history, physical, and radiographic) and treatment (operative and nonoperative) for this problematic disorder.

ETIOLOGY/CLASSIFICATIONS

Neck pain has been reported in the literature to occur in 66% of all individuals at some point during their lifetime.^{1,2} The most common cause of axial neck pain is age-related arthritis of the cervical spine. The degeneration of the cervical spine associated with osteoarthritis has been coined cervical spondylosis and is found in most aging individuals.^{2,3} Cervical spondylosis can have many presentations including axial neck pain, radiculopathy, myelopathy, or any combination of these symptoms. Unlike axial neck pain, the pathogenesis of radiculopathy and myelopathy are well understood and are related to compression of the cervical nerve roots or the spinal cord, respectively.

There are modifiable and nonmodifiable risk factors that have been shown to be associated with axial neck pain. Nonmodifiable risk factors include age, gender, and genetics. Modifiable risk factors associated with axial neck pain include tobacco use, low physical activity, sedentary work position, repetitive work, and precision work.⁴

Although the mainstay of treating axial neck pain is nonoperative, there have been several articles that advocate surgical intervention with beneficial results when the correct indications exist.^{2,5-9} Nonoperative modalities are commonly used with good results, but neck pain can be recurrent with 50–85% of people reporting recurring neck pain within 5 years of the initial event.⁴

The Task Force on Neck Pain and Its Associated Disorders in 2009 proposed a classification system to describe four different grades of axial neck pain in order to define a consensus on the severity of the axial neck pain when designing research and future health care policy.⁴ The classification is based on patients' subjective evaluation of pain and the clinician physical examination and radiographic evaluation. The classification is outlined in Table 38.1.

EVALUATION

The successful treatment of axial neck pain greatly depends on identifying the source of pain. There are many causes of axial neck pain including muscular strains, ligamentous

Table 38.1: Classification of axial neck pain.

<i>Grades</i>	<i>Signs, symptoms, and treatments</i>
Grade I neck pain	No signs or symptoms of structural pathology. Minor interference with daily activity. Responds to minimal intervention
Grade II neck pain	No signs or symptoms of structural pathology. Major interference with daily activity. Requires pain relief and early activation/intervention
Grade III neck pain	No signs or symptoms of structural pathology, but some neurological signs such as decreased reflexes, sensory changes, and/or weakness that warrants further radiographic workup
Grade IV neck pain	Signs or symptoms of major structural pathology, such as fracture, myelopathy, neoplasm, or systemic disease; requires prompt investigation and treatment

sprains, degeneration of the cervical disks, facet joint degeneration/arthritis, upper cervical and occipital/cervical arthritis, and rheumatoid patients with synovial erosions and instability.

Muscle strains and ligamentous sprains are usually made as a diagnosis of exclusion after structural diagnoses have been ruled out. They are usually associated with poor posture/ergonomics, work and personally related stress, traumatic injury such as a whiplash injury, and/or chronic muscular fatigue. Muscular pain can also develop secondarily, as a protective mechanism, to another primary source of pain coming from the shoulder, scapular dyskinesis, temporomandibular joint, and cervical pathologies including malignancies.^{10,11} The exact physiology of muscular/ligamentous pain generation is not fully understood but is thought to be secondary to the sensitization of the free nerve ending found in the muscular/ligamentous units.

Degeneration of the intervertebral disks is a normal part of aging and is associated with spondylosis, however, while most people eventually have degeneration of their intervertebral disk, not everyone presents with clinically significant axial neck pain. The peripheral portions of the cervical disks contain nerve fibers and endings from the sinuvertebral nerve that may be responsible for pain generation, especially with degeneration.^{12,13}

Facet joints (also known as zygapophyseal joints) are synovial joints that contribute to the posterior column on the cervical spine. Facet joints have been shown to cause

axial neck pain in experimental models. In an in vivo study evaluating the facet joints, normal patients with no axial neck pain had their facet joints injected with normal saline and patients responded with neck, head, and shoulder pain.¹⁴ This pain distribution was reversed when anesthetic injections were placed blocking the dorsal primary rami that is responsible for pain recognition in the facet joints.¹² These studies both demonstrate that the facet joints can be a source of axial-neck pain.

Upper cervical and occipital-cervical junctional arthritis can cause axial neck pain and occipital headaches. In another injection study, the authors demonstrated reproducible pain patterns with injections into the atlanto-occipital and atlantoaxial joints.¹⁵ In particular, patients can develop osteoarthritis of the C1-2 joint that can cause severe pain in the suboccipital joint region exacerbated by axial rotation¹⁶ (see Fig. 38.4).

Another generator of pain is irritation of the greater occipital nerve, a branch of the C2 nerve. The C2 nerve can be compressed or chemically irritated with atlantoaxial arthritis or pannus formation from rheumatoid disease. Rheumatoid disease is also known to cause axial neck pain caused by a multitude of pathologies including atlantoaxial instability, superior migration of dens and basilar invagination, and subaxial instability.

Although uncommon, upper cervical nerve compression at C3 or C4 from the C2/3 or C3/4 level does not typically radiate to the extremities and must be ruled out with magnetic resonance imaging (MRI) and diagnostic nerve root injections. Upper cervical nerve compression should not be confused with axial neck pain that is facet or disc related.

History and Physical Examination

As with many maladies in clinical medicine, the history and physical examination are of utmost importance. Axial neck pain and whiplash-associated disorder (WAD) typically present with posterior midline tenderness that can radiate to the shoulder and occiput. Stiffness and headaches are very common and so are descriptions of warmth and tingling.¹⁷ Patients with osteoarthritis of the C1-2 lateral mass joints can have severe pain with axial rotation of the head. Typically, these patients point to their suboccipital region lateralizing to the side of the arthritis. These patients will demonstrate significant decrease in their range of motion and increasing pain while turning toward the affected side.

One should do a careful neurologic examination to rule out pain in a dermatomal distribution, changes in sensory

patterns in the upper extremities, and blunting of reflexes. Myelopathic signs including a positive Hoffman's examination (flexion of thumb and index finger after rapid middle finger distal interphalangeal joint flexion), clonus (repetitive plantar flexion of ankle after forced dorsiflexion of ankle) or a present Babinski reflex (great toe extension after stroking plantar foot surface). If any of these findings are noted on physical examination further radiographic work-up is necessary to rule out spinal cord compression. Patients with axial neck pain typically do not display such findings. In patients who present with radicular or myelopathic symptoms and axial neck pain, the neurologic symptoms take priority in the treatment regimen.

Radiographic Imaging

Radiographic imaging for general axial neck pain can be very misleading because of its sensitivity in identifying abnormalities that may not be contributing to the current symptoms. Studies of patients between 50- and 65-year-old have shown a 79% incidence of disc space narrowing, end plate sclerosis, or osteophytes.¹⁸ Another study evaluating MRI in asymptomatic subjects demonstrated that in patients under 40 years of age there was a 14% incidence of bulging/herniated disks, foraminal stenosis, disc space narrowing, or abnormal cord signal change.¹⁹ The same study demonstrated an incidence that was double (28%) if the patient was over 40 for the same findings.¹⁹ The oversensitivity of radiographic imaging must be taken into account when examining patients with axial neck pain and imaging should be avoided if there is a normal neurological examination and no concern for trauma or instability. The National Emergency X-ray Use Study (NEXUS) is an excellent clinical study that was designed to determine the indication for imaging in patients with traumatic injuries and concern for cervical spine injury. National Emergency X-ray Use Study was a multicenter, prospective observational study designed to determine what clinical criteria indicate the need for radiographic imaging of the spine in blunt cervical spine trauma patients. The study had over 34,000 patients with blunt trauma to the head and neck. The study evaluated five clinical criteria that included midline cervical tenderness, focal neurological deficits, normal cognition, level of intoxication, and painful and distracting injuries (Table 38.2). The study demonstrated that out of the 34,000 patients, there were 818 cervical spine injuries, and of these 818 injuries, 810 were detected using these criteria, resulting in only 8 injuries being missed. This equates to a negative predictive value of 99.8% and a sensitivity of 99%.

Table 38.2: NEXUS clinical criteria.

Five components to clear cervical spine

- (1) No midline cervical tenderness
- (2) No focal neurologic deficit
- (3) Normal alertness
- (4) No intoxication
- (5) No painful, distracting injury

The criteria led to a reduction in the use of unindicated radiographs by 12.9%. The final conclusion of the NEXUS study was that there was an extremely low probability of c-spine injury if all five criteria were met.^{20,21} While this study was designed to determine if emergency medicine doctors should obtain advanced imaging, it also applies to the clinicians in primary care and surgical spine clinics. In a fully conscious patient with cervical trauma/WAD, the spine can be cleared with very high confidence using the same five clinical criteria. If any of the criteria are not met then radiographs should be obtained.

When history and physical examination is concerning for the diagnosis of C1-2 lateral mass arthritis, an open-mouth odontoid view of the cervical spine should be performed. Joint space narrowing secondary to loss of articular cartilage can be easily seen (see Fig. 38.4). If an open-mouth odontoid view cannot be obtained easily, CT scans can be performed to confirm the diagnosis. Occasionally, in the absence of joint space narrowing, MRI can often show inflammation of the C1-2 joint on the short inversion time inversion recovery (STIR) images.

TREATMENT

Nonoperative Treatment

Nonoperative therapy should always be the first line of treatment once structural instability and neurological compromise are ruled out. There is a paucity of high-quality evidence for the nonoperative treatment of axial neck pain. The Task Force on Neck Pain and Its Associated Disorders performed a meta-analysis of the literature reviewing over 31,000 citations regarding axial neck pain and what they found was that they had a difficult time creating any consensus statements due to the variability of the disorder, treatment modalities and outcomes.⁴ Nonoperative modalities include medical therapy, physical therapy, general health promotion, injection therapy, and radiofrequency ablation. There is a lack of clinical studies to support many of these modalities and much of the research has focused on low-back pain treatment.

Table 38.3: Nonoperative modalities.

<i>Modalities with clinical literature to support use</i>	<i>Modalities with NO clinical literature to support use</i>
Early return to normal activities ^{16,23,27}	Immobilization ^{27,31}
Supervised exercises and physical therapy ^{25,28}	Transcutaneous electrical nerve stimulation ^{16,28}
Chiropractic manipulation and mobilization ^{16,27,29,30}	Cervical traction ^{16,28,30,31}
Pulsed electromagnetic field therapy ^{27,30,31}	

Medical treatment is usually one of the first treatments for axial neck pain. There are multiple medications that can be used. Tylenol can be used in doses from 2 g to 4 g per day. It must be avoided in patient who are elderly, have a history of alcoholism/liver disease, taking other medications metabolized by the liver, and can still be toxic at recommended doses in these populations.²² Nonsteroidal anti-inflammatory drugs (NSAIDs) are also a first-line medication. They must be used with care because they have been shown to cause gastric ulcers and bleeding especially in the elderly. COX-2 inhibitors are recommended over traditional NSAIDs in the geriatric population.²³ These drugs should be used especially when the cause of the axial neck pain is thought to be arthritic or inflammatory in nature. Muscle relaxants have been shown to be efficacious in axial neck pain that is associated with neck spasms. They are, however, habit forming and have several side effects including nausea, somnolence, and decreased respiratory drive. Muscle relaxants are not recommended for the use in acute WAD injuries because of limited evidence of efficacy.^{17,24} Opioids are extremely efficacious in axial neck pain but should only be used for acute onset neck pain and should not be treatment modality for long-term chronic pain.²⁵ There are several side effects including physiologic dependence, constipation, sedation, and nausea. Antidepressant medications are widely used and have been documented in the literature to be efficacious for chronic pain syndromes and are frequently used in recalcitrant axial neck pain.^{23,25-27} There is often associated depression in patients with chronic axial neck pain that may also be helped with the use of antidepressant medications.

Physical modalities are often used for the treatment of axial neck pain and there is a wide range of interventions available. The literature once is diverse with regard to supporting their use and efficacy (Table 38.3).

Modalities with Clinical Evidence

Early return to usual activities has been shown to be clinically helpful especially in WAD.^{17,24,28} Supervised exercise and physical therapy have been shown efficacious for the treatment of acute onset axial neck pain and chronic neck pain.^{26,29} Chiropractic manipulation and mobilization have been shown to provide short-term relief of axial neck pain.^{17,28,30,31} Pulsed Electromagnetic Field Therapy has been shown to cause significant reductions in pain and increase in cervical range of motion in several high-quality studies.^{28,31,32}

Modalities with Little Clinical Evidence

Immobilization has been shown to provide no benefit in three studies for use in axial neck pain.^{28,32} Its use has only been recommended for 3 days or less when treating for WAD and if used beyond this has been shown to prolong disability.^{17,24} Transcutaneous electrical nerve stimulation and therapeutic ultrasound, while reported by most patients to relieve pain during treatment, have had several studies demonstrate no evidence of effect with regard to curative effects.^{17,29} Cervical traction, while widely used by physical therapists and as home units, has multiple high-level studies showing no long-term effect for its use in axial neck pain.^{17,29,31,32}

It is important to counsel patients about overall health with regard to weight, smoking cessation, and aerobic exercise. In epidemiologic studies axial neck pain is associated with overall poor general health status including obesity.³³⁻³⁵ There are, however, no clinical studies showing a direct correlation with weight loss and the reduction of axial neck pain. There have been a multitude of studies looking at the relationship between back pain and smoking. Since there are no clinical studies specifically looking at smoking and axial neck pain, results extrapolated from the axial low back pain literature should be examined with caution. Nonetheless, a large meta-analysis of over 47 epidemiologic studies concluded a direct correlation between smoking cessation and decreased axial back pain.³⁶ For this reason, we always counsel our axial neck pain patients on weight loss and smoking cessation. Aerobic exercise is also an important treatment modality in patients with axial neck pain, and there have been multiple studies demonstrating its effectiveness.³⁷⁻³⁹

Injection Therapy

There are a host of injection techniques that can be utilized for axial neck pain including trigger point, facet, nerve

root, and epidural injections. The literature is equally split in favor and against the use of these types of injection for axial neck pain with most publications only recommending their use in patients with true radiculopathy.^{40,41}

Operative Treatment

Accepted criteria for surgical intervention for axial neck pain exists mainly when the axial neck pain associated with a concurrent diagnosis of radiculopathy, myelopathy, or instability in the cervical spine. Indications for surgical intervention for axial neck pain alone are less clear and are more to the discretion of the practitioner and the patient's wants and needs. Most practitioners will only reserve surgical interventions for axial neck pain in patients who have exhausted all other conservative measures over a 6–12-month time period. Historically, results for surgical intervention of axial neck pain have demonstrated satisfactory results from 63% to 73% in patients.^{42–46} There are several recent articles in the literature that support surgical intervention for recalcitrant axial neck pain with good to excellent results being demonstrated. Palit et al. prospectively collected data on 38 consecutive patients who underwent anterior cervical discectomy and fusion for axial neck pain without signs/symptoms of radiculopathy or myelopathy.⁷ Their results showed that there was a significant reduction in visual analog scale neck pain scores and Oswestry disability questionnaire scores. Almost 80% of the patients were satisfied with their outcomes at 53 months of follow-up. Their data also demonstrated that there was not a difference between workers compensation claims and private insurance patients with regard to improvement. In another clinical study Ratliff et al. retrospectively studied 27 consecutive patients who underwent surgical intervention for axial neck pain without radiculopathy/myelopathy.⁸ In their series they had over 85% patient satisfaction, with over 95% stating they would repeat the surgical procedure for their neck pain. While these studies are subjected to selection and recall bias, they provide insight into outcomes associated with surgical management of axial neck pain. Overall, the literature suggests that operative treatment of degenerative disc disease in the cervical spine is more successful than in the lumbar spine. In addition, patients with recalcitrant pain due to C1-2 osteoarthritis may benefit from a C1-2 posterior arthrodesis and have been reported to have good results.¹⁶

CASE EXAMPLES

Case 1

Case 1 is a 50-year-old healthy female who presented with 1 year of axial neck pain without radicular or myelopathic symptoms. Radiographs showed multilevel degenerative disc disease without instability (Fig. 38.1). An MRI demonstrated multilevel disc degeneration without significant foraminal or central stenosis. She was treated for 2 years with conservative measures including physical therapy, chiropractic manipulation, and NSAIDs. She presented back to our office 3 years after initial onset of axial neck pain with recalcitrant axial neck pain and disability. A repeat MRI (Figs. 38.2A and B) demonstrated a small central herniation at C5/6 without foraminal stenosis. Since she failed a complete nonoperative course and did not have external motivators, she was offered surgical treatment. Her post-operative radiographs are seen in Figure 38.3. At 3-month follow-up, all of her axial neck pain had resolved. This case is an exception for our practice as neck pain from multilevel

Fig. 38.1: Preoperative films of patient with axial neck pain and no signs of radiculopathy or myelopathy. Note the kyphosis in the cervical spine along with the multilevel degenerative disc disease.

Figs. 38.2A and B: Preoperative magnetic resonance imaging of patient. Sagittal film (A) shows multilevel degenerative disc disease but no significant stenosis. Axial image (B) demonstrates small central herniation at C5/6 but no foraminal stenosis.

Fig. 38.3: Postoperative films of patient with axial neck pain who failed 3 years of conservative therapy. Note the restoration of cervical lordosis and incorporation of anterior iliac crest bone graft at 3 months post-operation.

Fig. 38.4: Preoperative films of patient with axial neck pain and no signs of radiculopathy or myelopathy. Note the severe osteoarthritis in the right C1/C2 lateral mass complex (arrow).

degenerative disc disease is almost never treated operatively. Careful patient education of expectations following degenerative disc disease surgery is mandatory.

Case 2

Case 2 is a 55-year-old female with 3 years of axial neck pain localized to the right suboccipital region. On physical

examination, she had limited rotation to the right side. She had no signs or symptoms of radiculopathy or myelopathy. Open-mouth odontoid and lateral view of the cervical spine are seen in Figures 38.4 and 38.5. Severe osteoarthritis is noted in the right C1-2 lateral mass articulation. The patient underwent multiple nonoperative modalities including physical therapy with traction, epidural steroid injections, NSAIDs, and immobilization. The patient was ultimately

Fig. 38.5: Preoperative films of patient with axial neck pain and no signs of radiculopathy or myelopathy. Note the severe osteoarthritis in the C1/C2 lateral mass complex (arrow).

Figs. 38.6A to C: Anteroposterior, lateral, and open-mouth odontoid views status post C1/2 posterior spinal fusion using the Harm's technique for severe C1/2 osteoarthritis.

treated with a C1-2 posterior arthrodesis using the Harm's technique⁴⁷ (Figs. 38.6A to C). As anticipated, she ultimately lost 50% of her flexion/extension and axial rotation but had total resolution from her axial neck pain.

CONCLUSION

Axial neck pain is a ubiquitous complaint in primary care and most spine surgeon's offices. There are a plethora of pathologies that can cause axial neck pain usually related to biomechanical changes associated with aging and associated cervical spondylosis. However, acute onset axial neck pain from trauma and recalcitrant neck pain associated with rheumatologic disorders and malignancies must be ruled out. The patient history and physical and radiographic imaging, if warranted, can usually lead the practi-

tioner to make a diagnosis of the pathogenesis of the axial neck pain.

The available treatment modalities are abundant, but the evidence to support most modalities is lacking. Luckily most episodes of axial neck pain, without any significant intervention, will recover over time. When recalcitrant axial neck pain has failed nonoperative modalities surgical intervention may be warranted depending on the source of the axial neck pain. Unfortunately, there are no prospective, randomized studies in the literature evaluating the operative outcome of patients with axial neck pain. However, there are several studies in the literature that demonstrate improved clinical and functional outcome for patients with recalcitrant axial neck pain that have failed multiple conservative measures.

KEY POINTS

- Axial neck pain is ubiquitous in the general population with approximately 70% of the population having an episode of axial neck pain within their lifetime.
- Conservative treatments including physical therapy, structured exercise, weight loss, smoking cessation, and chiropractic manipulation have been shown to improve axial neck pain.
- Surgical treatment should be reserved for recalcitrant axial neck pain patients that have completed most of the noninvasive modalities and who persistently have symptoms of axial neck pain.

- » Injection Management

INTRODUCTION

Cervical radiculopathy is a dysfunction of a cervical spinal nerve root arising from compression and inflammation of the root near the cervical neural foramen. Clinically patients present with pain in the neck and one arm, with a combination of sensory and motor loss, with or without reflex changes in the affected nerve root distribution.^{1,2} The reported incidence of cervical radiculopathy is between 0.85 and 3.5 per 1,000 population with peak incidence around 50–54 years of age.^{3–5}

The most common cause of radiculopathy is neural foramen encroachment due to cervical spondylosis with hard osteophyte compression and/or a soft cervical disc herniation. Unlike in lumbar disc herniation, a true herniation of the nucleus pulposus is uncommon in cervical disc disease.⁶ Other factors such as hypertrophied facet joint, uncovertebral joint hypertrophy, disc protrusion, and spondylotic spurring of vertebral body also often play a variable role either individually or in combination. Less common causes of cervical radiculopathy are intra- or extra-spinal tumors, traumatic root compressions or avulsions, synovial cyst, meningeal cysts, and dural arteriovenous fistulae.²

PATHOPHYSIOLOGY

The primary pathology of cervical spondylosis starts within the intervertebral disc and later progresses to secondary mechanical changes in the surrounding facet joints and

soft tissue structures. Decreasing water content from 90% at 30 years to <70% by the eighth decade, changes in the ratio of proteoglycan to collagen and keratin sulfate to chondroitin sulphate in nucleus pulposus makes the disc more compressible and less elastic.⁷ This subjects the annular fibers to excessive compression and shear forces, causing weakening and tearing of their outer layers, potentially leading to a soft disc herniation. Reduction in the intervertebral disc height also leads to ligamentum flavum buckling, osteophyte formation, hypertrophy of the uncovertebral and facet joints. This process leads to encroachment of the neural foramen that is referred to as hard disc.² The origin of pain in cervical radiculopathy is multimodal and includes release of inflammatory mediators during the disc prolapse and compression of the dorsal root ganglion (Fig. 39.1).^{8,9}

Clinical Presentation

Acute, subacute, and chronic types of cervical radiculopathic presentations have been reported.² Acute cervical radiculopathy occurs in the setting of soft disc herniation in younger age group individuals. Patients without persistent symptoms with pre-existing cervical spondylosis present with subacute radiculopathy. They develop insidious symptoms, which are often polyradicular in nature. Acute and subacute radiculopathies that fail to respond to treatment progress to chronic radiculopathy.

Pain radiating to the arm is the most common symptom followed by sensory deficit, neck pain, diminished

Fig. 39.1: Pathophysiology of cervical nerve root compression.

reflexes, and motor deficit in a series of 800 patients with cervical radiculopathy (Table 39.1). Sensory symptoms like paresthesia and numbness often do not follow a sensory dermatomal pattern. In acute cervical radiculopathy, patients experience pain in the myotomal distribution rather than a distal dermatomal distribution.² Common patterns of presentation are shown in Table 39.2.

Tanaka et al.¹¹ proposed that neck or periscapular pain often precede arm or finger symptoms in cervical root compression based on their experience during diagnostic root injections (Fig. 39.2). As the needle is inserted around the root, patients perceive neck or scapular pain first followed by arm or finger pain. It is also common in clinical practice to see patients with only neck or scapular pain unaccompanied by radicular symptoms in the arm or fingers. Pain in the suprascapular region indicates C5 or C6 radiculopathy, pain in the interscapular region corresponds to C7 or C8 radiculopathy, and pain in the scapular region to C8 radiculopathy (Fig. 39.3).

Clinical Examination

Local pathologies around the shoulder and scapular region should be excluded before attributing the pain to cervical root involvement. To differentiate cervical radiculopathy from other sources of pain, provocative tests specific to cervical nerve roots have been explained. Spurling's sign is elicited by hyperextending the neck and rotation toward the symptomatic side, resulting in reproduction of the arm

Table 39.1: Clinical presentation of cervical radiculopathy.¹⁰

Arm pain	99.4%
Sensory deficit	85.2%
Neck pain	79.7%
Reflex deficits	71.2%
Motor deficits	68%
Scapular pain	52.5%
Anterior chest pain	17.8%
Headaches	9.7%
Anterior chest and arm pain	5.9%
Left-sided chest and arm pain	1.3%

pain. This maneuver diminishes the available area in an already compromised neural foramen, leading to further nerve root compression. This test is specific but not sensitive for cervical radiculopathy. Axial compression test, in which compression over the skull may diminish the height of the foramen and reproduce symptoms, is a less reliable provocative sign. Valsalva maneuver also increases the radicular pain (Fig. 39.4).

Davidson et al. described shoulder abduction sign wherein patient experiences relief of arm pain with shoulder abduction.¹² Shoulder abduction brings about pain relief by shortening the course of the nerve and relieving the compression (Fig. 39.5).

Systematic and proper clinical examination in cervical radiculopathy would lead us to the level of compression and root involved. The most common nerve roots involved in cervical radiculopathy are the C6 and C7 roots due to C5-C6 and C6-C7 disc pathology, respectively. Patients with C7 radiculopathy present with pain along the posterior aspect of the shoulder, over the triceps and dorsal aspect of middle finger. Triceps weakness may not be noticed by the patient until it becomes severe, since elbow extension is aided by gravity. The C6 nerve root is the second most common nerve root involved in cervical radiculopathy and the patient usually presents with pain radiating from the neck to lateral aspect of forearm, thumb and the index finger and dorsal aspect of web space between them. Although many groups of muscles are supplied by the C6 root, wrist extensors are predominantly affected. C5 radiculopathy, which is the next most common root involved, results from pathology at the C4-C5 disc and presents with pain along the lateral aspect of the shoulder associated with numbness. Deltoid and supraspinatus are the primarily affected muscles, weakening the shoulder abduction.

Table 39.2: Cervical radiculopathy and associated sensory, motor, and reflex disorders.

Disc level	Nerve root	Dermatome-pain distribution and sensory loss	Motor weakness	Reflex
C1-C2	C2	Posterior occipital headaches, temporal pain	None	None
C2-C3	C3	Supraclavicular, suboccipital and posterior auricular regions	Trapezius, levator scapulae, strap muscles, sternocleidomastoid, diaphragm	None
C3-C4	C4	Infraclavicular and posterior cervical regions, posterior shoulder	Trapezius, rhomboids, levator scapulae, diaphragm	None
C4-C5	C5	Superolateral arm pain	Deltoid, supraspinatus and infraspinatus, biceps	Biceps
C5-C6	C6	Lateral forearm, thumb and index finger	Wrist extensors, biceps, brachioradialis	Brachioradialis (supinator), biceps
C6-C7	C7	Medial scapula, posterior arm, dorsum of forearm, third finger	Triceps, wrist flexors, and finger extensors	Triceps
C7-T1	C8	Shoulder, ulnar side of fore arm, and pain in ring and fifth finger	Finger flexors (flexor digitorum superficialis and profundus, flexor polices longus) lumbricals 3 and 4	None
T1-T2	T1	Axillary and pectoral region, medial arm and	Hand intrinsics, Horner's syndrome	None

The presentations of other nerve roots are explained in Table 39.2. Upper motor neuron signs such as exaggerated reflexes, increased tone, Hoffman's sign, and finger escape sign along with gait of the patient should always be examined, as cervical myelopathy may be associated with cervical radiculopathy and needs further evaluation.

Differential Diagnosis

There are various conditions around the shoulder and neck region that could produce symptoms mimicking cervical radiculopathy. Meticulous clinical examination along with appropriate investigations would guide the differentiation

Fig. 39.4: Spurling's test.

of these conditions from cervical radiculopathy. The differential diagnosis and their differentiating features are explained in Table 39.3.

Rarely, cervical radiculopathy might occur in conjunction with other nerve entrapment syndromes, making the clinical diagnosis difficult. Of particular importance is the association of carpal tunnel syndrome that not only causes diagnostic difficulties but also increases symptoms as compression of an axon at one location impairs the axoplasmic flow and makes it more sensitive to compression in another distal location (double crush syndrome).¹³

Diagnostic Modalities

Plain radiographs provide valuable information regarding sagittal balance, reduction of the disc height, presence of uncovertebral osteophytes, loss of intersegmental alignment and instability. However, the poor correlation between clinical symptoms and degenerative changes seen in radiographs and inability to visualize the neural elements restrict the usefulness of plain radiography.¹⁴ Magnetic resonance imaging (MRI) is the gold standard for evaluation of patients with cervical radiculopathy.¹⁵ Careful analyses of both axial and sagittal images can provide considerable information about the cause, severity, and location of the nerve root compression. Use of an oblique series that images perpendicular to the foramen can be useful, as a typical sagittal MRI is not orthogonal to the foramen. Magnetic resonance imaging is valuable in differentiating a soft disc

Fig. 39.5: Davidson's shoulder abduction sign.

from a hard disc or in determining the presence of both. Patients who remain symptomatic even after 4–6 weeks of conservative treatment, patients with significant neurological deficit, signs of myelopathy, or patients with suspicion of other pathologies like tumor, or infection require an MRI. The high frequency of abnormal MRI findings in asymptomatic individuals should also be kept in mind before taking any clinical decision (Figs. 39.6A and B).¹⁶

Computed tomography (CT) has a limited but important role in patients who are claustrophobic and in those with contraindications to MRI. Computed tomography scan is particularly useful to assess foraminal encroachment by osteophytes and in combination with intrathecal contrast (CT myelography) it gives accurate assessment of both the spinal and neural anatomy.¹⁷ Computed tomography myelogram is also indicated in patients with adjacent segment disease who have previous instrumentation in whom metal artifact is a problem. Other than clearly depicting bony causes of central or foraminal stenosis, MRI has the advantage of better delineation of pathology of stenosis with a lower radiation hazard (Fig. 39.7).

Electrophysiological studies, namely nerve conduction velocity and electromyography (EMG), play only an adjuvant role in patients in whom the symptoms and MRI findings do not correlate. Nerve conduction velocity that analyses the amplitude, distal latency, and the conduction velocity is an important tool in differentiating various nerve entrapment syndromes from cervical radiculopathy. Presence of fibrillation potentials and positive sharp waves at rest in EMG is suggestive of muscle denervation. These findings often take 3 weeks to occur after the onset of neural

Table 39.3: Differential diagnosis of cervical radiculopathy.

<i>Differential diagnosis</i>	<i>Nerve root mimicked</i>	<i>Differentiating feature of the condition</i>
Rotator cuff tear and other shoulder affections	C5	<ol style="list-style-type: none"> 1. Shoulder abduction might be weak but other muscle groups (biceps) supplied by C5 root not involved 2. Tenderness of shoulder joint with restricted movements 3. Shoulder-specific provocative tests include Hawkin's sign, Open-Can sign and Speed's test 4. Not associated with any sensory component or reflex loss 5. Severe catching pain when the patients' abducts the arm above 90°
Acute brachial plexus neuritis (AKA, Parsonage-Turner syndrome)	C5, C6	<ol style="list-style-type: none"> 1. Severe pain in neck, shoulder, and arm that is followed by marked weakness in C5 and C6 myotome within few days to weeks 2. In cervical radiculopathy, pain and neurological findings occur simultaneously 3. Nerve conduction study might be needed in some cases to differentiate
Suprascapular nerve entrapment	C5	<ol style="list-style-type: none"> 1. Pain in the shoulder and weakness of the shoulder girdle are common complaints. Atrophy of the supraspinatus and infraspinatus muscles seen 2. Not associated with weakness of other C5 innervated muscles such as deltoid, biceps, and pectoralis major
Carpal tunnel syndrome	C6, C7	<ol style="list-style-type: none"> 1. Nocturnal dysesthesia and hypoesthesia present distally only in palmar aspect of hand (first three digits) 2. Weakness and atrophy of thenar and first two lumbricals 3. Phalen's test may be positive and Tinel's sign may be present.
Anterior interosseous nerve entrapment	C8	<ol style="list-style-type: none"> 1. Pain in the proximal forearm 2. Weakness or paralysis of the flexor pollicis longus, the flexor digitorum profundus to the index and long fingers, and the pronator quadratus- positive pinch sign 3. Finger flexors of ulnar two fingers will be normal 4. No sensory loss
Ulnar nerve entrapment—cubital tunnel syndrome	C8	<ol style="list-style-type: none"> 1. Tingling or “pins and needles” sensation in the little and ring fingers 2. Tenderness along the medial aspect of the elbow 3. Positive ulnar Tinel's sign
Thoracic outlet syndrome	C8, T1	<ol style="list-style-type: none"> 1. Intermittent paresthesia in the C8 and T1 region provoked by Roos test (rapid flexion extension of fingers with shoulder abducted to 90° and externally rotated to 90°). C8-T1 radiculopathy is very rare 2. Reproduction of symptoms with rotation of the neck to the contralateral side and tilting of the head to the contralateral side in contrast to cervical radiculopathy where the opposite produces the pain (Spurling's test) 3. Hyperabducting the arm to 180° pulls the components of the neurovascular bundle around the pectoralis minor tendon, the coracoid process, and the head of the humerus aggravating the symptoms of thoracic outlet obstruction, while in cervical radiculopathy hyperabduction relieves the pain (Davidson's test)

injury. Denervation potentials appear sooner in paraspinal muscles and the presence of it differentiates cervical radiculopathy from brachial plexitis.¹⁸ Electromyography can also help identify patients with a double crush syndrome.

NATURAL HISTORY OF CERVICAL RADICULOPATHY

Most studies quoted in the literature regarding the natural course of cervical radiculopathy suggest that the majority

of the patients improve with conservative treatment. In a multicenter trial for cervical radiculopathy, 75% of patients with pain, irrespective of the presence of paresthesia, improved in 4 weeks with conservative care. The use of traction or cervical collar did not influence the outcome. Lee and Turner in their study of 51 patients with cervical radiculopathy observed that 45% of patients had only one episode of pain without any recurrence and only 25% of patients had persistent radicular pain.¹⁹ Heckmann et al. compared conservative and surgical treatment in patients

Figs. 39.6A and B: T2W MR image showing C5-C6 left posterolateral soft sequestered disc herniation in sagittal (A) and axial (B) imaging.

Fig. 39.7: Computed tomography myelogram showing left posterolateral hard disc prolapse.

with primary acute cervical radiculopathy secondary to herniated cervical discs. Sixty-five percent of patients were successfully treated conservatively and only 35% needed surgery.²⁰ In contrast, Gore et al. reviewed conservatively treated patients with cervical radiculopathy and found that 50% had persistent symptoms at 15-year follow-up and stated that, while short-term nonoperative treatment may alleviate symptoms of cervical spondylotic radiculopathy, with long-term follow-up, many patients might have recurrence of symptoms.²¹ There is no literature support for the widespread belief that degenerative cervical radiculopathy might eventually progress to spondylotic myelopathy.¹⁹ There is still a lack of literature regarding

the long-term outcome of patients treated conservatively and studies that have followed up patients with soft and hard disc separately.²²

Goals and Treatment Options

The main objectives in the treatment of cervical radiculopathy are to (1) reduce pain, (2) improve functional status, (3) resolve neurological deficits, and (4) prevent recurrence.

The initial treatment must be planned in such a way as to achieve the above goals. Unless patients have severe intractable pain or significant neurological deficits, a 6–12-week conservative trial of treatment is mandatory. Cervical radiculopathy rarely requires urgent surgical intervention.

Patient Education

All patients must be educated about the natural history of the disease, anatomical considerations, response to treatment, side effects of specific treatments, their expectations during the recovery period, and the indications for surgery. Avoidance of activity that will aggravate pain, maintaining proper posture and neutral positioning of the neck during daily activities, must be emphasized. This will avoid irritation of the nerve root and reduce the intensity of treatment recommended.

The conservative line of management can be classified into noninvasive and invasive modalities. Noninvasive modalities include medication, rest and immobilization, cervical traction, ice/heat therapy, transcutaneous electrical nerve stimulation (TENS), massage therapy, physical

therapy, and alternative medicine. Interventional treatments include cervical epidural steroids and transforaminal or selective nerve root injections.

Medications

Medications used include nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, muscle relaxants, anti-depressants, anticonvulsants, and steroids.

Analgesic medication may be prescribed to reduce pain and improve activity tolerance. First-line medication consists of acetaminophen or an NSAID. Nonsteroidal anti-inflammatory drugs inhibit the enzyme cyclo-oxygenase (COX) and the COX pathway, thereby inhibiting the production of prostaglandins. They act as analgesics in lower dose and as an anti-inflammatory agent in higher doses, thereby addressing the inflammatory component of radiculopathy. The main concern is toxicity related to gastrointestinal (peptic ulcer), renal (acute renal failure), and cardiovascular systems (water retention and hypertension). Patients at high risk are those on long-term treatment, the elderly, those taking concomitant corticosteroids, and patients with pre-existing peptic ulcer disease. Alternative analgesia in the form of opioids, nonopioids, and newer COX-2 inhibitors should be considered in this group of patients. COX-2-selective NSAIDs are highly specific inhibitors that leave the COX-1 pathway undisturbed, thereby not inhibiting the gastroprotective properties.²³ The controversy continues regarding the use of NSAIDs and the increased risk of atherothrombotic events like myocardial infarction and stroke at higher doses. The exact mechanism for this variable increased risk of cardiovascular events with selective COX-2 inhibitors is not clearly understood, but research suggests that it could be related to the extent of COX-2 inhibition by drugs that do not block COX-1 completely.²⁴ Though there is no study comparing the efficacy of NSAIDs over acetaminophen in cervical radiculopathy, there are significant benefits noticed in patients with severe osteoarthritis of the hips and knee.^{25,26} Diclofenac is associated with a 40–60% increase in risk of cardiovascular events compared to nonuse of NSAIDs;^{27,28} however, naproxen has reported to have a relatively lower risk.²⁹

If an acute episode of radiculopathic pain is particularly severe, narcotic medication may be appropriate. The advantages of opioid analgesics over the nonopioid (acetaminophen) and NSAID medications are that they do not have an end organ like hepatic and renal toxicity, respectively. The vast majority of patients readily discontinue narcotics once an acute pain episode has resolved

and there is no ceiling effect. Concerns regarding the risk of respiratory depression and addiction have limited the use of narcotic opioid analgesia in chronic pain. The dose of the opioid can be reduced with combination of acetaminophen that is effective as a multimodal therapy. Previous psychological disorders, major depression, and substance abuse are contraindications for opioid use. Neuropathic pain, however, may be somewhat opioid resistant.

Significant paraspinal muscle spasm can usually be adequately treated with a soft cervical collar. A minority of patients may benefit from a brief trial of muscle relaxants, such as norflex, cyclobenzaprine, or diazepam. Muscle relaxants reduce the paraspinal and trapezius muscle spasm that may worsen the radicular pain symptoms. A meta-analysis of placebo-controlled trial of cyclobenzaprine reported significant improvement in mixed populations of neck and low back pain.²⁴ The most common of these adverse effects are sedation and dry mouth. These medications may, however, have a higher addiction profile than narcotics and treatment should not be prolonged beyond 2 weeks.

In the subpopulation of patients with pain-induced depression, antidepressant medication, such as amitriptyline, may also reduce neuropathic pain. The therapeutic efficacy may also be related to either their inhibitory effect on serotonin and/or epinephrine uptake. The common side effects of antidepressant medication are drowsiness, weight gain, dry mouth, dizziness, constipation, and urinary retention. Their use in an acute setting is questionable but patients who have sleeping difficulty and acute depression may benefit.

Anticonvulsant medications like gabapentin are now widely used to treat neuropathic pain syndromes, including radiculopathy. Several studies have shown the usefulness, efficacy, and improved quality of life with gabapentin. Some of the side effects are dizziness and somnolence. It is recommended to start at a low dose, 100–300 mg/day, and gradually increases until either pain control is achieved or adverse effects occur within the recommended range.³⁰ Pregabalin has been shown in studies to provide equivalent efficacy to gabapentin, however, at much lower doses. Pregabalin at lower doses has a much higher bioavailability and rapid absorption, thereby reducing the dose-related side effects. Monotherapy or add-on pregabalin is associated with substantial pain relief in patients with cervical and lumbar radiculopathy.³¹

The use of oral corticosteroid medications for treatment of acute radiculopathy is controversial. Theoretically, their efficacy is due to a potent anti-inflammatory effect

through inhibition of phospholipase A2 and decrease in arachidonic acid and prostaglandin production on irritated nerve roots. Patients often demonstrate rapid and dramatic reduction in acute pain levels. A tapering dose of methylprednisolone can be given for a period of 1–2 weeks. The toxicity of corticosteroids is limited when these drugs are used for short periods; however, behavioral changes, such as depression and peptic ulceration, can occur. Liberal use of steroids should be balanced with the risk of osteonecrosis particularly in younger patients.

Rest and Immobilization

During the period of acute pain and spasm, a short period of bed rest is thought to reduce the pain by reducing the inflammation around the nerve root and muscle spasm. Instead of absolute bed rest, most authors prefer limitation of specific activities such as hyperextension of neck and rotation of neck to ipsilateral side to prevent foraminal narrowing and pain exacerbation.³² Using a soft cervical collar closed in the front to maintain the neck in slight flexion for a short period of time can be beneficial.³³ A nighttime collar helps maintain proper neck position and limits unconscious neck movements. Although collars have shown good benefit in management of cervical radiculopathy,³⁴ their potential negative effects are weakness and muscle atrophy, promotion of contractures, and psychological dependence.³⁵ Ideally, collars should be weaned off in a period of 2–3 weeks. Isometric neck exercises during this period can reduce muscle atrophy.³⁶ There is no evidence to suggest that using a collar would alter the duration of symptoms or alter the need for surgical treatment.³⁷

Cervical Traction

Traction is thought to relieve pain by enlarging the intervertebral foramina, separating apophyseal joints, relaxing muscle spasm, and reducing intradiscal pressure.³⁸ One study has shown an 81% relief of pain in mild-to-moderate cervical spondylosis, though the patient groups were mixed. Cervical traction may be intermittent, continuous, or sustained and can be applied by manual methods, motorized or pneumatic devices. The usual traction force applied is between 10 and 20 lb for 15–20 minutes with mild neck flexion at 20°. ³⁹ Traction with the neck in extension may worsen the arm pain by narrowing the neural foramen. Suboptimal response during initial traction application or worsening of symptoms often warrants discon-

tinuation. Although cervical traction is widely used, there is little evidence to support its use.⁴⁰

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation uses electrical currents for nerve excitation produced by portable stimulators. Two or more electrodes are placed over the skin and a battery operated unit is used to produce currents at a frequency of 10–50 Hz. The TENS machine can modulate the pulse width, frequency, and intensity of the current required for treatment of pain. Though there is some evidence for the management of low back pain, the literature does not contain enough information to indicate that these devices provide any significant benefit for the treatment of cervical radiculopathy.

Massage Therapy

Massage can relieve painful muscle spasms associated with radiculopathy by increasing cutaneous blood flow, mobilization of tissue, relief of muscle hypertonicity, and reduction of swelling. Although there is a paucity of literature to support its use anecdotally, it can be helpful in the subacute phase when muscle spasm can accompany radiculopathy.

Physical Therapy

Physical therapy has not been shown to alter the natural history of cervical radiculopathy. After a period of rest isometric exercises to strengthen the cervical musculature are instituted. Isometric exercises involve muscle strengthening without painful motion of the cervical spine. However, isometric contraction of local musculature, most often the trapezius, may result in increased loading of the intervertebral discs and exacerbate pain. Aerobic conditioning may also be helpful in relieving symptoms. Aerobic exercise for individuals with cervical spine pain is generally limited to low-impact activities. Stationary bicycling, walking, use of a Stairmaster machine, and other nonimpact aerobic exercises are preferred to avoid jarring the cervical spine. Active range of motion and resistive exercises may be added as the pain improves. It is best for the patient to be involved in a whole-body exercise program with special attention to the shoulder girdle and neck musculature. In cervical disc disease, special attention should be given to the scapular stabilization muscles, including the trapezius, deltoids, latissimus dorsi, and rhomboids. The final step in the rehabilitation protocol is a home exercise program. Postural

education, ergonomics, and lifestyle modifications may also be beneficial in preventing recurrences.

Alternative Medicine

Acupuncture is a treatment in which thin hair-like needles are placed at specific points in the body to prevent or treat illnesses. Stimulating these points is believed to promote the body's natural healing capabilities and enhance its function. It has gained popularity in clinical practice for pain management. One of the principles by which acupuncture works is by stimulating the central nervous system to release neurotransmitters and hormones that dull pain, boost the immune system, and regulate various body functions. While there is anecdotal evidence that acupuncture may be beneficial for cervical radiculopathy, there lacks good clinical evidence to support its use.

INJECTION MANAGEMENT

Injections are an alternative to other noninterventional methods to relieve radicular pain. Cervical epidural steroid injections, transforaminal epidural injections, and selective nerve root injections are good treatment options when patients fail to respond to medication and conservative care. Injections are also a diagnostic tool when there is a mismatch between symptoms and radiologic findings. An injection of local anesthetic and corticosteroids is used in both an epidural and a selective nerve root injection.^{41,42}

Cervical Epidural Steroid Injection

Cervical epidural steroid injections can be performed via an interlaminar or transforaminal route. The cervical transforaminal epidural technique is carried out utilizing an oblique radiologic view of the targeted intervertebral foramen. This view is obtained with the patient in a supine position. The skin is prepared and draped. The C2-C3 foramen is used to count down to the appropriate level to be injected. Once the targeted foramen is identified with fluoroscopy then the skin is infiltrated with 1% lidocaine. A 25G spinal needle is advanced to the posterior-inferior edge of the foramen and slightly redirected into the foramen and advanced a few millimeters. Anteroposterior (AP) and lateral pictures are taken to verify the position. In the AP view, the needle tip should not extend further medially than the midpoint of the adjacent pedicle. Once the position is confirmed 0.5 mL of contrast is introduced under live fluoroscopy; 1–2 mL of 0.5 or 1% lidocaine and 1–2 mL

Fig. 39.8: Oblique views of a transforaminal injection revealing epidural spread.

Source: Wang LH, McKenzie-Brown AM, Hord A. Handbook of Carm fluoroscopy-guided spinal injections. Taylor & Francis Group, LLC; 2006. Chapter 8: Cervical Injections. p. 217.

of corticosteroid are then injected allowing the medicine to cover the nerve root and epidural space (Fig. 39.8).

A cervical interlaminar epidural injection can be performed in the seated, lateral, or prone position. The desired interlaminar space is identified with a fluoroscope. The injection is usually performed in the midline usually in the C7-T1 or the C6-C7 space. The skin is prepped and anesthetized with 1% lidocaine. An 18G or 22G Tuohy needle is inserted into the epidural space using the standard epidural technique. Anteroposterior and lateral fluoroscopic views can be used intermittently to identify the depth of the needle. Once the needle has reached the epidural space, 1–3 mL of nonionic contrast is injected to confirm the spread of dye; 1–2 mL of 0.5 or 1% lidocaine and 1–2 mL of corticosteroid are injected (Fig. 39.9).

Selective Nerve Root Block

Cervical selective nerve root injections are specific to one nerve and are distinctly different than epidurals. They have been reported to relieve pain in 28.6–81% in various series.⁴³ Pain relief was more effective in the first few weeks compared to 6 months.⁴³ A meta-analysis to determine efficacy is difficult because the dose and combination of steroid and local anesthetic use varied. Selective nerve root injections are more commonly used to isolate a specific symptomatic nerve root level as the medication does not reach the epidural space. The technique for a selective nerve root block is very similar to the transforaminal

Fig. 39.9: Interlaminar needle placement with a catheter threaded and contrast lateralized to the left side. The needle was inserted at the C7/T1 interspace.

Source: Wang LH, McKenzie-Brown AM, Hord A. Handbook of Carm fluoroscopy-guided spinal injections. Taylor & Francis Group, LLC; 2006. Chapter 8: Cervial Injections. p. 213.

epidural injection except that the needle tip is placed in the more lateral aspect of the foramen. A small amount of contrast is injected, and if it spreads along the nerve root and not into the epidural space 1–2 mL of local anesthetic and steroid is given.

Selective nerve root blocks in the cervical spine have been associated with several neurological complications including vascular injury, cerebral infarction, and spinal cord injury.⁴⁴ Several precautions must be taken to avoid these serious complications. Vertebral artery injection causing cerebral infarction is due to embolization of the particulate steroids injected. Use of betamethasone and dexamethasone rather than methylprednisolone and triamcinolone can help reduce this complication as they are manufactured at smaller particle sizes in suspension form. To prevent direct injury to the cord real time, AP views are advised and the tip of the needle must be located half-way between the medial and lateral border of the lateral mass, as insertion beyond this depth risks puncturing the dura. Caution should also be taken when injecting the contrast although the nonionic monomer radiographic contrast medium, iohexol (Omnipaque 300), is relatively safe (Figs. 39.10A and B).

KEY POINTS

- Radicular pain and sensory disturbance are the most common presentation of cervical disc prolapse that improve most of the time with conservative management.

Figs. 39.10A and B: Cervical nerve root block. (A) Contrast is instilled through the needle to confirm appropriate tip placement and to exclude intravascular location (arrow showing contrast outlining the nerve root). (B) The medication is injected under fluoroscopic guidance to confirm dilution of the contrast.

Source: Blankenbaker DG, Davis KW, Choi JJ. Selective nerve root blocks. *Semin Roentgenol.* 2004;39(1):24–36.

- The C6 and C7 roots are the most common levels to be affected.
- Magnetic resonance imaging is the gold standard for diagnosing and differentiating a soft and hard disc.
- Conservative treatment is multimodal and includes a combination of medical and physical therapy.
- Injection therapy gives good local anti-inflammatory relief for acute radiculopathy

INTRODUCTION

Cervical radiculopathy is typically caused by disc herniation or spondylotic foraminal stenosis (Figs. 40.1A to C). However, in the degenerative cervical spine, both pathologies may be present simultaneously. Symptoms include radicular arm pain, neck pain, weakness in specific myotome, diminished sensation in specific dermatome, and altered reflexes.¹ The indication for surgery is persistent pronounced pain with a reduced quality of life despite conservative treatment for >12 weeks. In addition, uncontrollable pain and/or neurological deficits may justify surgical treatment at an earlier time. Due to the overwhelming importance of manual dexterity, any sudden or progressive significant reduction of strength in the C6-8 roots may be a consideration for earlier surgery. Depending on the location of the stenosis or disc herniation and accompanying degenerative changes, clinical symptoms can include radiculopathy or myelopathy and justifies surgical intervention.^{2,3} Prior to surgery, patients should have appropriate imaging with MRI or CT scan. Patients should also undergo flexion-extension radiographs to identify instability.

The goal of surgery is to relieve neural compression and stabilize instability. Mechanical compressive pathology may include collapse of the intervertebral disc, sclerosis

of the vertebral endplates, osteophyte formation, facet degeneration, central or uncoforaminal stenosis. The surgical strategy is dependent on the pathological lesion. The long-term goal is a secure and lasting decompression of the neural structures and prevention of recurrent compression.

In the last 60 years, various surgical techniques have been developed. These include the anterior cervical discectomy and fusion (ACDF), anterior cervical discectomy without fusion (ACD), anterior foraminotomy without discectomy, artificial disc replacement (TDR), or posterior laminoforaminotomy. Furthermore, minimal-invasive, endoscopic, and percutaneous techniques have been developed.⁴

ANTERIOR CERVICAL DISCECTOMY AND FUSION

The anterior approach was described in the late 1950s by Cloward.⁵ Smith and Robinson simultaneously described the fusion technique with minimal modification of the original description.⁶ The anterolateral skin incision is typically <3–4 cm. It is our preference to use a horizontal skin incision located at the level of the pathology for one, two, or three level procedures. Four level anterior approaches warrant a vertical incision along the border of the sternocleidomastoid. After incision of the platysma and identification of the sternocleidomastoid muscle as a lateral

Figs. 40.1A to C: Disc herniations or spondylotic foraminal stenosis can cause cervical radiculopathy.

boundary, the index disc space can be located by blunt dissection. Gently lifting the carotid sheath structures and midline airway structures during the approach can facilitate identification of the interval. It should appear as wispy, white fascial tissue that is avascular. The surgeon should be able to palpate the carotid pulse lateral to the approach. At C3/4, a more lateral incision and approach is necessary due to the large size of the midline structures. The longus colli muscles are elevated and a self-retaining retractor is placed after appropriate radiological verification of the correct disc level. To keep the retractors from migrating, we use a small 1 lb weight tied to the retractor on the carotid side, and a 2 lb weight tied to the esophageal side to prevent

anterior migration of the retractors. Following retractor placement, the anterior longitudinal ligament is sharply incised. The anterior part of the annulus and the nucleus is then removed. Distraction of the interspace either with a Caspar-distractor or a Cloward intervertebral body spreader should be performed to facilitate decompression. Microscope or Loupe magnification can be used to help safely resect the posterior annulus and the posterior longitudinal ligament. Central and neuroforaminal decompression can be performed under direct visualization. The herniated disc material can be removed and coexisting osteophytes are resected with Kerrison punches or by using a high speed burr.

In order to restore and maintain segmental lordosis, as well as to achieve a predictable fusion, the majority of surgeons recommend an anterior discectomy with fusion (ACDF). This is a result of earlier studies that describe significant subsidence, kyphosis, and collapse if an anterior discectomy without fusion (ACD) is performed.⁷

Fusion of the segment can be obtained by either using cages or grafts with or without additional plating. The use of a polymethylmethacrylate (PMMA) spacer bears the risk of nonunion and is discouraged.^{7,8} When using iliac crest bone autograft, donor site morbidity must be considered and discussed with the patient.⁹ Cages show bony fusion rates equivalent to those of the iliac crest grafts.¹⁰⁻¹² Differences in clinical outcome between synthetic cage materials (PEEK or titanium) have not been demonstrated.^{13,14} There is ongoing discussion about the possible advantages

of the additive application of a plate or the use of a cage-plate construct. The use of cages without additional security ("stand-alone") carries the risk of subsidence, anterior migration, and formation of a local kyphosis.^{15,16} The use of an additive plate or a cage-plate construct can prevent kyphosis in the later course and may result in better clinical results (Figs. 40.2A to F).^{17,18} It has been shown that in case of two or more levels, the additional use of a plate results in significantly higher fusion rates.¹⁹ On the other hand, some negative side effects of the plates like higher costs, postoperative hoarseness and swallowing difficulties, implant loosening, adjacent segment degeneration, adjacent level ossification disease have to be considered.²⁰ The development of new cage-plate constructs is intended to reduce some of these disadvantages.²¹ It should be emphasized that use of a plate for a single-level

Figs. 40.2A to F: A 59-year-old man with disc prolapse C6/7 with right C7 radiculopathy. Anterior cervical discectomy and fusion with an integrated cage construct (2-year follow-up).

fusion has not been shown to increase union rate but has been shown to reduce progressive kyphosis.²²

The short-, medium- and long-term results of ACDF with fusion rates of >90% and significant improvement of clinical symptoms are well documented.²³⁻²⁵ All other procedures must, therefore, be measured by that standard.

Details of anterior cervical approaches are also discussed in Chapter 36 of this textbook.

TOTAL DISC REPLACEMENT

The implantation of an artificial disc is an alternative treatment option for cervical radiculopathy in the absence of contraindications (Figs. 40.3A to H).²⁶ The maintenance of the mobility of the operated segment is desirable in principle and can be generally achieved with current prostheses. Interestingly, despite maintaining motion at the operative level, there has not been a demonstrated reduction in adjacent segment disease with cervical arthroplasty over fusion.²⁷ Contraindications for cervical disc prosthesis are listed in Table 40.1.^{26,28-30} In general, patients with existing spondylosis and facet joint degeneration are not candidates for cervical arthroplasty. During surgery, care should be taken to resect endplates, posterior bony osteophytes, and the apophyseal ring sparingly, as otherwise a “spontaneous” fusion of the segment may occur.³¹

In order to take advantage of the biomechanical properties of a TDR, placement of the prosthesis in the middle of the vertebral body is indispensable. Intraoperatively, this must be checked with image intensifier in both anterior and lateral views. In the selection of the prosthesis height, care should be taken not to distract the segment excessively. Postoperative intervertebral heights of 5–7 mm are sufficient.³²

The current available data shows equal to better results of cervical TDR in comparison to ACDF in the first 4–5 years after surgery.³³⁻³⁶ However, the lack of long-term results demonstrating superiority of a TDR to ACDF remains to be seen.^{37,38}

Cervical arthroplasty is also covered in Chapter 95 of this textbook.

ANTERIOR FORAMINOTOMY WITHOUT DISCECTOMY (UNCOFORAMINOTOMY)

In the setting of neuroforaminal stenosis caused solely by a herniated disc or by osteophytes, anterior uncoforaminotomy is a surgical alternative. This procedure eliminates

the need for an interbody fusion while accomplishing direct removal of the offending lesion. It is also an option for patients who have undergone either or both an anterior and a posterior cervical disc surgery with unsuccessful relief of their radiculopathy.

During this procedure, the medial part of the longus colli muscle is incised and retracted. The uncovertebral joint is then exposed (Fig. 40.4). The foramen is enlarged by access through the uncinat process. Intraoperative visualization is limited significantly with this approach so finding a sequestered disc herniation can be considerably more difficult. In addition, the relative proximity of the vertebral artery and of the sympathetic plexus may lead to injury of either structure. The vertebral artery is directly lateral to the uncovertebral joint and anterior to the nerve root. Prior to attempting this procedure, we recommend carefully reviewing the anatomy of the vertebral artery at the level of surgery, as well as the management of a potential vertebral artery injury. Although the uncinat is not a true joint, disruption of the uncovertebral joint may lead to subsequent autofusion of the operative segment. There is some technical heterogeneity in the procedure description in that some practitioners emphasize resection of the medial portion of the uncovertebral joint and some emphasize resection of the lateral portion of the uncovertebral joint. It is clear that resection of the entire uncovertebral joint destabilizes the spine and creates potential for kyphosis, scoliosis and collapse.³⁹⁻⁴¹

POSTERIOR FORAMINOTOMY

Patients who suffer from isolated radiculopathy caused by a laterally situated soft sequestered disc without longstanding chronic neck pain are ideal candidates for posterior foraminotomies. The intervertebral height should be well preserved, and there should be no associated spinal instability. Other contraindications are significant kyphosis, massive disc herniation compressing the nerve root, and marked spondylosis. Additionally, extensive axial neck pain is considered a relative contraindication to posterior procedure. Through a posterior medial or paramedian access the lamina and the facet joint of the affected segment are exposed, and then opened with a high speed burr (Fig. 40.5). In our practice, we carefully undercut the caudal aspect of the cranial level lamina then undercut the cranial aspect of the more caudal lamina. For instance, at C6/7 we undercut the C6 lamina initially and locate the spinal canal with a nerve hook at that level. Then we undercut the cranial aspect of the C7 lamina working laterally with Kerrison

Figs. 40.3A to H: A 37-year-old woman with disc prolapse C5/6 with left C6 radiculopathy. Anterior discectomy and total disc replacement (2-year follow-up with mobile prosthesis).

rongeurs. Ultimately, the medial aspect of the C7 superior articular process is undercut as that corresponds to the region of highest stenosis. The nerve root is then exposed and carefully mobilized to reach the sequestered fragment.

Fusion of the segment is usually not necessary. Concerns with laminoforaminotomy include the possibility for persistent axial pain and postoperative segmental instability if >50% of the facet has been removed. The clinical

Table 40.1: Contraindications for cervical total disc replacement.^{18,20-22}

Age > 60 years
Significant segmental kyphosis (> 11°)
Functional instability (translation > 2 mm in flexion/extension, vertebral fracture)
Intervertebral disc height < 3 mm
Marked spondylosis of the index segment (osteoarthrosis, facet degeneration)
Long-lasting severe neck pain
Cervical myelopathy
Congenital spinal stenosis (< 10 mm)
Active infection of the cervical spine
Tumor of the cervical spine
Osteoporosis
Ossification of the posterior longitudinal ligament
Systemic infection or metabolic diseases
Known allergy to parts of the implant
Severe adipositas (BMI > 40)
Pregnancy
Alcohol or drug abuse

(BMI: Body mass index).

Fig. 40.4: Uncovertebral joint becomes visible after incising the longus colli muscle.

results are similar to those of other procedures with satisfactory to excellent results in 85–90% of cases.⁴²⁻⁴⁴

Minimally invasive posterior cervical foraminotomy is also covered in Chapter 132 of this textbook.

Fig. 40.5: The facet joint is exposed, and then opened with a high speed burr.

■ ENDOSCOPIC TECHNIQUES

Endoscopic techniques exist for both anterior and posterior approaches. Due to limited visibility and working space, only well-localized sequestered herniations can be recovered safely. In principle, it is possible to perform a spinal fusion endoscopically.⁴⁵ Because of a flat learning curve with significant potential complications endoscopic interventions are considered very challenging. Although the reported results are good, superiority to the standard procedures has not been proven. Endoscopic techniques have therefore been established in only a few centers and are carried out by only a few surgeons experienced in this technique.⁴⁵⁻⁴⁸

■ PERCUTANEOUS TECHNIQUES

Percutaneous techniques are typically based on thermal or chemical induced reduction of disc herniations (laser discectomy, nucleoplasty, chemonucleolysis) or percutaneous removal of disc tissue. They are not suitable for the treatment of sequestered disc herniations and should therefore be reserved for contained disc herniations. Although the success rate of these techniques are reported to be >80%, none of these techniques has been proven to be superior in comparison to conservative or surgical therapy.^{13,49,50}

■ COMPLICATIONS

The surgical treatment of cervical spondylotic radiculopathy can be regarded as a safe procedure with a major

Table 40.2: Surgical complications of the cervical spine.⁴³⁻⁵⁵

Overall complication rate 3–5%, severe complications <1%
Overall infection rate 3–6%
Infections due to anterior approach 0.9–1.6%
Injuries of trachea and esophagus <1%
Paralysis of the recurrent laryngeal nerve: transient 6–8%; permanent 0.2–3%
Horner's syndrome <1%
Dysphagia: early postoperative up to 50%; permanent 12–33%
Paralysis of the superior laryngeal nerve 1–2%
Injury of the thoracic duct <1%
Spinal cord injury 1–3%
Epidural hematoma <1%
Postoperative liquorrhea 0.5–3%
Vertebral artery injury <1%
Implant-related complications (dislocation, loosening, subsidence, failure) 1–10%
Pseudarthrosis after fusion <10%

complication rate below 5%.⁵¹ The most frequent complications are caused by implants, followed by nonunions and postoperative dysphagia. For the latter, especially in the early postoperative period rates of over 50% are reported.⁵²

The anterolateral approach generally represents a relatively simple and safe way to reach the anterior cervical spine. From anatomical point of view, the approach should be taken from the left to avoid damage of the recurrent laryngeal nerve. However, several studies have demonstrated no difference in rate of recurrent laryngeal nerve injury between left and right sides.^{53,54} The posterior approach to the cervical spine does avoid the risk of injury to structures in the anterior neck region entirely, but is characterized by an increased risk of wound infection.^{55,56} Furthermore, development of chronic neck pain is possible. Endoscopic and percutaneous techniques carry a particularly high risk for complications and should therefore be used only by experienced surgeons. The possible complications and their frequency of anterior and posterior surgical techniques are listed in Table 40.2.⁵¹⁻⁶³

POSTOPERATIVE CARE

Long term use of postoperative orthotics is rarely necessary.²⁶ In case of an ACDF or TDR, a soft orthosis can be used until wound healing is complete or up to 6 weeks. Isometric

contraction exercises and physical treatment should be carried out until the release of the full range of motion. Thereafter, active muscle training can be started with the objective of restoring range of motion.

PROGNOSIS

The published long-term results of conservative and surgical procedures show satisfactory to good results.^{1,11-13,23-25,36} Ultimately, fusion occurs in many cases due to the natural course or by iatrogenic measures. Long-term results of the motion-preserving procedures are not yet available.

KEY POINTS

- Indications for surgical treatment include neurological deficits and ongoing pain despite 3 months of conservative therapy.
- Radiological findings must match clinical symptoms.
- The aim of surgery is to decompress the mechanically irritated neural structures.
- Anterior cervical discectomy and fusion is the gold standard with good-to-excellent clinical and radiological outcomes.
- Artificial disc replacement is promising as an equivalent alternative to ACDF although long-term data on structural longevity and reduction of adjacent level disease is unknown.

BACKGROUND

Cervical myelopathy represents the clinical syndrome of neurologic dysfunction arising from progressive subacute compression of the cervical spinal cord. Degenerative cervical spondylosis may result in compression of the spinal cord anteriorly secondary to disc-osteophyte complexes and/or posterior longitudinal ligament ossification, and may be potentiated by cervical kyphosis. Posteriorly, spinal cord compression may result from ligamentum flavum hypertrophy, in-folding of redundant ligamentum flavum, and facet hypertrophy, and may be similarly potentiated by cervical extension. Dynamic factors related to position and soft-tissue hypertrophy are more likely to result in symptoms when superimposed upon static congenital cervical stenosis, osteophytes, or bulging intervertebral discs.

The pathophysiology of cervical spondylotic myelopathy (CSM) is complex and likely multifactorial. Anatomic risk factors for the development of CSM are difficult to assess, as the proportion of the population with asymptomatic cervical stenosis is unknown.¹ Mechanical compression likely leads to irritation and inflammation of the neural elements, and this inflammatory cascade may result in demyelination and cellular injury. Anterior compression also likely leads to impaired vascular perfusion of both the spinal cord and nerve roots, likely potentiating the effects of mechanical irritation.² This frequently results in upper motor neuron findings that may be mixed with

a component of radicular pain or weakness (i.e. myeloradiculopathy). Cervical spondylosis is also frequently associated with a degree of segmental instability, and further injury to the spinal cord may occur secondary to altered biomechanics in the setting of pain and impaired proprioception. For the purposes of this chapter, only patients presenting with or diagnosed with myelopathy or myeloradiculopathy will be considered.

The diagnosis of CSM is established by the presence of long tract or upper motor neuron findings on clinical examination that correlate with an appropriate anatomic site of spinal cord compression. The diagnosis is typically confirmed by radiologic findings, either indirectly in the case of plain radiographs or computed tomography (CT) demonstrating altered bony anatomy, or by direct demonstration of intraparenchymal signal changes on magnetic resonance imaging (MRI). In mild cases of myelopathy, the neurologic manifestations may be subtle and diverse making the diagnosis challenging to establish. Symptom progression is often insidious and pain may be variably present. Making the diagnosis of CSM requires careful attention to the patient's history and physical examination. The critical aspect for the treating physician first lies in recognition, as these disease patterns can be confused with a more central process such as multiple sclerosis or a peripheral neuropathy such as cubital or carpal tunnel syndrome.³ In patients who develop cervical myelopathy associated with rheumatoid arthritis, early symptoms such as difficulty with manual dexterity are often missed

as they are attributed to the patient's systemic condition. Although appropriate imaging is mandatory for confirmation of CSM, the presence of overt clinical findings ultimately leads to the appropriate diagnosis. Brain in 1952 was among the first to comprehensively describe the various clinical findings and natural history of CSM.⁴ Clarke and Robinson, 4 years later, went on to further define the range of signs and symptoms in a large series.⁵ Results from both operative and nonoperative management were disappointing; however, this created a basis for an evolving treatment algorithm. In 1972, Nurick published a functional scale, which is still used today, that was able to grade the severity of symptoms and allow for longitudinal comparison for evaluating efficacy of treatment.⁶ Nurick looked at his own series of patients and found that 56% of patients improved with surgery compared to 40% with conservative management. Despite improved characterization of the disease, no clear consensus exists as to what constellation of clinical findings best define a patient with CSM, and moreover, those who will benefit from nonoperative management as opposed to surgical intervention.

CLINICAL EVALUATION

The typical clinical presentation of CSM is that of a patient with subtle gait disturbances and decreased functional dexterity of the hands. Frequently, a patient's family members or close associates may notice abnormalities of gait that have been attributed to other causes. Common hand symptoms include altered sensation that does not follow a peripheral nerve distribution (e.g. not carpal tunnel or ulnar nerve), difficulty button/unbuttoning clothes or undergarments, difficulty with identifying loose change in one's pocket, or difficulty with fine motor tasks such as opening doorknobs and manipulating small objects. More severe presentations will involve frank gait disturbances, motor weakness, and hyper-reflexia with possible spasticity. An individual patient's specific symptoms are dependent on his or her anatomic site(s) of compression, though mixed presentations are common in the setting of longstanding multilevel disease.

History

Cervical spondylotic myelopathy is the most common type of spinal cord dysfunction seen in patients who are >50 years old.⁶ Clarke and Robinson described three modes of progression with myelopathic symptoms over several weeks to several years.⁵ The authors reported on

120 patients with CSM and found that, although 75% of the patients had periods of stable symptoms, the majority demonstrated stepwise deterioration. Of the remaining patients, 20% had slow but steady progression and 5% had initial deterioration of neurologic function followed by long periods with no progression of symptoms. Sadasivan et al. followed 22 patients with CSM and found that all of the patients showed steady and progressive worsening of symptoms over an average of 6 years.⁷ The natural history of CSM suggests that the majority of patients will have progressive neurological stepwise deterioration in the long term.^{2,8-10} While the typical course is one of general stepwise deterioration in function, some patients have no progression in symptoms while others have a rapid decline.

Neck pain is variably present with CSM: Emery et al. reported that 85% of patients recalled some degree of neck pain over time,¹¹ while Crandall et al. reported less than half his patients had neck symptoms.¹² Given the variability, it is likely that this symptom is a consequence of the degenerative changes as opposed to direct compression of the neural elements themselves.

Subtle changes in coordination in the hands are commonly associated with CSM. Patients may initially complain of functional alterations in the hands or simply changes in sensation. The functional changes may be due to lack of coordination or muscle weakness. Fine motor tasks such as writing or buttoning a shirt may become difficult. These characteristic findings ultimately led Ono to coin the phrase "myelopathy hand."¹³ The practitioner must keep this in mind to help differentiate myelopathy from neuropathy or nerve compression syndromes like carpal tunnel syndrome or cubital tunnel syndrome. Voskuhl and Hinton reported on a series of 13 patients with initial presentation of hand numbness, with the majority of these patients describing symptoms in a glove-like pattern.¹⁴ Sadasivan reported 72% of the patients in his series had diminished upper extremity dexterity on initial presentation.⁷

Upper extremity radiculopathy is also common in patients with CSM. This may exist on one or both arms and has been found to occur in up to 40% of cases.¹² The same degenerative changes that may contribute to central stenosis, such as an osteophyte or protruded disc, may also encroach into the neural foramen and cause nerve root compression and myeloradiculopathy.

Perhaps the most common initial finding in patients with CSM is subjective gait instability. Because symptoms are often subtle and insidious in onset, they may not be readily acknowledged by the patient and instead are

often noted by family or friends. Ambulation at night may be especially difficult due to the combination of impaired proprioception and limited visual feedback in low-light conditions. As the dysfunction progresses, a slower pace and wider-based gait are often noted. Ultimately, the use of assistive devices may be needed. Ambulatory dysfunction with a risk of fall is of particular concern in this patient population, as those with severe CSM are at higher risk for acute spinal cord injury with fall, typically presenting as a central cord syndrome.¹⁵

Bowel and bladder dysfunction are also possible with CSM, though these are typically a late manifestation of the disease. Clarke and Robinson reported rates of bladder and bowel dysfunction of 40% and 2.5%, respectively,⁵ while Hukuda's series of 269 patients with CSM demonstrated 15% with bladder and 18% with bowel dysfunction.¹⁶ Urinary urgency, frequency, hesitation, incontinence, and retention are all possible, and fecal incontinence can occur in a small percentage of patients.

Physical Examination

The clinical assessment of CSM begins with the observation of gait along with ease of motion and coordination of movements. Many combinations of muscle weakness and atrophy, sensory changes, and reflex abnormalities of upper and/or lower extremities can occur. Gait abnormalities occur in CSM patients up to 90% of the time. The classical myelopathic gait is often described as broad-based and lacking a smooth, rhythmic motion. While severe alterations in gait may be obvious, subtle deficits may only be elicited through a specific activity, such as heel-to-toe (tandem) walking. Strategies to enhance stability during ambulation and compensate for loss of proprioception often occur. These usually include the widening of one's stance base and shortening of the step length.^{10,17} As neurologic symptoms progress, ataxic type gait patterns can ensue and this can lead to falls and injury as well as the potential need for assistive devices or a wheelchair.

In addition to observation of gait with provocative testing, a thorough neurologic evaluation, including motor and sensory testing, assessment of reflexes and special testing for coordination and balance, must be completed for both upper and lower extremities. Flaccid weakness and hyporeflexia generally occur at or above the level of compression, with spastic weakness and long tract signs occurring below the level of the lesion. Multiple spinal cord tracts may be affected. Motor weakness results from

ipsilateral or bilateral involvement of the lateral corticospinal tracts. Compression of the spinothalamic tract results in contralateral or bilateral loss of pain and temperature sensation. Ipsilateral or bilateral loss of vibratory sensation and proprioception may be present due to dysfunction of the dorsal spinocerebellar tracts. Paresthesias in a dermatomal pattern are indicative of compression of the dorsal roots. Upper extremity signs and symptoms generally occur in a unilateral fashion while the lower extremity signs and symptoms are more often bilateral.^{5,10}

Focused examination of the extremities begins with observation. In the upper extremities, muscle wasting may be present, particularly in the hand. A thorough sensory and motor examination is necessary of all the cervical dermatomes and myotomes, as well as provocative testing of proprioception, vibratory sense, pain, and temperature. Ono et al. reported a 90% involvement of the hand in spondylotic patients with myelopathy.¹³ Two tests useful for examination of the myelopathic hand include the finger escape sign and the grip and release test, and are both indicative of corticospinal tract dysfunction. The finger escape sign is tested by having an individual hold their fingers in an extended and adducted position for as long as possible. A positive sign in a myelopathic patient is when the ulnar-sided fingers begin to flex and abduct within 30 seconds. The grip and release test is performed by having the patient repeatedly form a fist and release it as quickly as possible. A normal response is the ability to perform the action 20 times in 10 seconds. In the myelopathic patient, the action is slow, uncoordinated and often incomplete.¹⁰ Pathologic reflexes of the upper extremities, such as the Hoffman's sign, may also be present in CSM. The Hoffman's sign is elicited by immobilizing the patient's middle phalanx of the middle finger [keeping the proximal interphalangeal (IP) joint extended] and applying a quick stretch to the flexor digitorum profundus (through the distal IP joint). A positive response occurs with a flexion response of the distal IP joint of the thumb and index fingers. Care must be taken in interpreting this finding as this response is present in up to 5% of the general population. Denno et al. described a variation of the Hoffman's sign, termed the dynamic Hoffman's sign.¹⁸ The test is performed three times with the neck in neutral, flexed and extended position, and may be an earlier indicator of cervical myelopathy. The inverted radial reflex may also be indicative of myelopathy. It is elicited by testing the deep tendon reflex of the brachioradialis: a positive response occurs with a depressed brachioradialis response coupled

with a hyper-reflexive long finger flexor response. A positive inverted radial reflex has been shown to be more specific for cervical cord compression than a positive Hoffman's sign.¹⁷ Pathologic reflexes may also be present with compression of the upper cervical region. The pectoralis reflex is assessed by tapping the pectoralis insertion at the deltopectoral groove. It is considered positive if there is a reflexive response of adduction and internal rotation about the shoulder. Watson et al. showed this response to be highly specific for compression at the C3-C4 level.¹⁹ The scapulohumeral reflex has also been described for evaluating upper cervical pathology. The reflex is tested by tapping the spine of the scapula or the acromion in a downward fashion. The test is considered positive if the scapula elevates and/or the humerus abducts. Shimizu et al. showed that all patients in their series with neural compression between the posterior arch of C1 and the caudal edge of C3 had a positive scapulohumeral reflex.²⁰

A comprehensive motor and sensory examination of the lower extremities should also be performed. Lower extremity findings are characteristically bilateral with hyper-reflexia and evidence of unilateral weakness or sensory changes in a dermatomal pattern. Depressed lower extremity reflexes may alert the practitioner to concomitant lumbar pathology. Long tract signs, although not specific to CSM, may be present. The Babinski response is commonly evaluated. This is performed by briskly advancing the pointed end of a reflex hammer along the lateral plantar aspect of the feet from the heel toward the toes. A normal response is curling of the toes, whereas an upgoing great toe is indicative of upper motor neuron involvement. Testing for clonus should also be performed by forcefully dorsiflexing the feet, which can also indicate upper motor neuron pathology. The crossed adductor response should also be tested. This involves tapping the medial femoral condyle on one side of a patient, who is positioned in slight hip abduction. An abnormal response occurs when the contralateral leg adducts reflexively. Harrop et al. showed this response to be present in approximately 75% of myelopathic patients.²¹

Coordination testing may also reveal evidence of CSM. The Romberg's test is often used to assess subtle deficits in balance. The patient stands with their arms forward flexed and supinated with their eyes closed. A loss of balance is considered a positive Romberg's test and can be indicative of posterior column dysfunction. The inability to perform rapid alternating movements such as

pronation and supination of the forearms is indicative of dysdiadochokinesia, again consistent with posterior column involvement. Finally, the jaw-jerk reflex can be tested. Although this is not a test for cervical myelopathy, it can be used to differentiate cervical versus cranial pathology. It is performed by tapping the chin with a reflex hammer. A pathologic response occurs when the jaw reflexively contracts, indicating possible supratentorial involvement.

There is increasing recognition that a subset of patients presents with tandem stenosis, which is typically described as simultaneous cervical and lumbar stenosis.^{22,23} The presentation of tandem stenosis can be a diagnostic challenge, as the effects of lumbar stenosis may mask the physical findings (i.e. hyper-reflexia) of the cervical stenosis. A detailed history is important, and in the patient presenting with lumbar stenosis, a history that elicits upper extremity symptoms merits consideration of cervical spine MRI.

Radiologic Evaluation

Plain Radiography

Anteroposterior, lateral, flexion, and extension plain radiographs of the cervical spine are routinely obtained for evaluation of the patient with CSM. Nonspecific signs of age-related spinal degeneration are typically observed, such as loss of disc space height and osteophyte formation. One should pay particular attention to the ratio of the sagittal diameter of the spinal canal relative to the diameter of the corresponding vertebral body, which typically is approximately 1.0 (Fig. 41.1). Pavlov et al. posited that a mean ratio of less 0.8 is suggestive of congenital cervical stenosis and a subsequent predisposition to spinal cord injury with minor trauma or degenerative changes.²⁴ Computed tomography images should also be assessed for possible signs of ossification along the posterior longitudinal ligament. Overall cervical alignment should be noted, as well as range of motion with flexion and extension. Careful attention should also be paid to any findings of segmental instability on flexion-extension views.

Magnetic Resonance Imaging

Magnetic resonance imaging has become the preferred modality for assessing the neural elements and surrounding soft-tissue structures. The typical sagittal diameter for the spinal canal is generally 17 mm between C3 and C7 and the average sagittal spinal cord diameter is 10 mm.²

Fig. 41.1: Lateral X-ray of the cervical spine demonstrating the Pavlov, or Torg, ratio measurement.

Relative cervical stenosis is present at sagittal diameters <13 mm, and absolute stenosis is present at diameters <10 mm.² On T2-weighted images, spinal cord irritation may present as an area of hyperintensity, termed myelomalacia (Fig. 41.2). If the corresponding regions are also dark on T1-weighted images, this may represent demyelination and portend a negative prognosis. It is hypothesized that the absence of low-signal changes on T1 may indicate that the damage is reversible.²⁵⁻²⁸ The transverse area of the spinal cord should also be assessed in addition to the degree of compression on sagittal images. Cross-sectional area of <30 mm² has been associated with worse prognosis in CSM.²⁵

Computed Tomography

Computed tomography scanning provides better visualization of the bony elements than MRI and is a complementary study, particularly for surgical planning. Ossification of the posterior longitudinal ligament is best visualized on CT. However, CT without contrast is suboptimal for visualizing the neural elements. Computed tomography with myelography provides good evaluation of intrinsic spinal cord compression, and may offer improved visualization of extrinsic compression of the nerve roots at their takeoff from the spinal cord. This modality may also be especially useful in cases where artifact from prior instrumentation precludes effective imaging with MRI.

Fig. 41.2: Sagittal T2-weighted magnetic resonance imaging of a patient with multilevel cervical stenosis in the setting of degenerative disease. Note the T2-signal hyperintensity lesion consistent with myelomalacia.

Differential Diagnosis

Due to the significant variability in the initial presentation of CSM, careful consideration must be given to other systemic or central nervous system processes capable of producing similar manifestations, as well as peripheral entrapment syndromes and/or coexisting compressive pathology in other regions of the spine. Careful attention to subtle complaints or symptoms that may seem inconsequential can assist in directing the clinician in decision making, physical examination, and obtaining advanced imaging studies that ultimately lead to the diagnosis. Examination of the extremities and/or electromyography with nerve conduction studies may help identify sites of peripheral nerve compression, resulting in seemingly-radicular pain, weakness, or atrophy. Central nervous system demyelinating disorders, such as multiple sclerosis and amyotrophic lateral sclerosis, may result in subtle but progressive neurologic findings, mimicking early stages of CSM. Movement disorders, such as Parkinson disease and Huntington disease, may also produce gait instability and difficulties with fine motor tasks. In addition, early mild cognitive impairment or dementia may impair a patient's awareness of symptom progression. Given the age-related nature of CSM, these conditions are commonly coexistent. Even in the presence of myeloradiculopathy with anatomically corresponding degenerative changes, the presence

of systemic or neurodegenerative disorders may affect the patient's prognosis with or without surgical intervention.

NATURAL HISTORY AND NONOPERATIVE TREATMENT

There is currently no noninvasive therapy that can arrest the progression of the degenerative changes leading to CSM. As such, the primary role of nonoperative treatment in CSM is to provide symptomatic relief of neck or radicular pain, and to maintain overall health and functional status. The true natural history of myelopathy is controversial, with the predominance of the literature comprised of retrospective case series. While many authors report a natural history of progressive neurologic decline with observation/medical treatment,^{15,29} other series have suggested that after initial decline there is a plateau that may not progress in mild cases.^{6,9} Even if a progressive decline in neurologic function over time is predicted, it is uncertain whether the relative risks of surgery outweigh the risks of disease progression in elderly patients with relatively mild symptoms. While risk factors such as age, radiologic findings, or disease severity have been examined, no consensus exists regarding their predictive value for CSM progression.

Medical management options for CSM include cervical orthosis, anti-inflammatory medications, corticosteroids, cervical injections (epidural, selective nerve root block, or facet), cervical traction, and narcotic or non-narcotic analgesics. The role of a cervical orthosis is to immobilize and stabilize the spine. The hypothesis is that the load sharing of the orthosis may alleviate axial neck pain, and the stabilization of the spine may alleviate spinal cord symptoms occurring secondary to dynamic compression (e.g. Lhermitte's sign). Patients with predominantly anterior pathology in the setting of posterior disc bulges and/or endplate spurring may benefit from immobilization in neutral or slight extension, whereas patients with predominantly posterior compression in the setting of infolding of the ligamentum flavum may benefit from immobilization in a slight degree of flexion. However, there is simply no substantive data regarding nonoperative trials that isolated cervical orthosis as a treatment variable for CSM. In the majority of patients, cervical orthoses are of limited morbidity, particularly if removed when eating and/or sleeping, although prolonged use may result in pressure ulcers of the occiput or upper cervical spine in elderly or incapacitated patients.³⁰ In addition, prolonged orthosis wear may result in deconditioning of the cervical musculature.

Nonsteroidal anti-inflammatory medications may alleviate axial neck pain in spondylotic patients via both an analgesic and anti-inflammatory effect. Nonsteroidal anti-inflammatory drugs (NSAIDs) are hypothesized to potentially alleviate myeloradicular pain by modulating the inflammatory cascade that is hypothesized to play a role in radiculopathy. There is a paucity of published literature on the role of NSAIDs in myelopathy. Particularly in the elderly population, NSAIDs may be associated with significant medical complications, and there is increasing recognition of potential cardiovascular side effects.³¹ Steroid injections (either epidural or selective nerve root) have numerous reports in the management of cervical radiculopathy. However, in the setting of myelopathy with spinal cord compression, the role of epidural injection is highly controversial and generally not recommended. There are no studies examining steroid injection or oral steroids as an independent variable for management of myelopathy.

Neck exercises (either self-directed or under the guidance of a trained physical therapist) to strengthen the neck muscles may be beneficial for the management of axial neck pain arising from cervical spondylosis. Cervical manipulation should not be performed in the setting of spinal cord compression with myelopathy.

There are few studies directly comparing operative to nonoperative management for treatment of CSM. Instead, prior studies consist primarily of retrospective observational case series with heterogeneous nonsurgical treatment. More recent studies have applied validated clinical grading criteria in an attempt to systematically assess for disease progression with nonoperative management. Matsumoto et al. described a nonoperative treatment regimen for mild myelopathy from cervical disc herniation consisting of 8 hours of daily cervical immobilization for 3 months, followed by intermittent orthosis use for another 3 months.³² The authors observed significant improvements in Japanese Orthopaedic Association (JOA) scores in 17 of 27 patients (59%). The remaining 10 patients demonstrated disease progression and ultimately underwent surgical intervention. In a subsequent study, the authors examined a larger series of 52 patients with cervical myelopathy due to CSM, ossification of the posterior longitudinal ligament, or disc herniation.³³ Nakamura et al. evaluated a variety of nonoperative treatments, including cervical orthotic immobilization, as halter traction, casting, and Crutchfield traction, in a series of 64 patients treated over 6 years.³⁴ Improvements of at least one

JOA grade were noted in the upper extremity in 55% of patients, and in the lower extremity in 57%, with worsening noted in only 3%. A subsequent long-term analysis over a mean of 6 years revealed that 34 of 53 (64%) maintained their functional status, while 19 (36%) deteriorated necessitating surgical intervention. Shimomura et al. reported a prospective cohort of 70 patients with mild CSM (JOA grade ≥ 13) undergoing a nonoperative treatment regimen consisting of 2 weeks of hospitalization with traction 8 hours per day followed by activity modification at home to minimize risk of fall.³⁵ Of the 56 patients (80%) included after final follow-up at 36 months, no statistically significant decrease in JOA scores was observed; however, 11 patients underwent surgical intervention on the basis of subjective deterioration. Risk factors for deterioration, including age, gender, radiologic developmental or dynamic factors, and abnormal T2-weighted signal on sagittal MRI, were evaluated. The authors concluded that non-surgical treatment of mild CSM produced acceptable outcomes, but that a site of circumferential compression seen on MRI was a risk factor for subsequent deterioration.

Several groups have attempted to directly compare outcomes with surgical and nonsurgical treatment of CSM. Sampath et al. performed a subgroup analysis of 62 patients with CSM from a larger nonrandomized series comparing surgical and nonsurgical interventions for a variety of degenerative conditions of the cervical spine. Nonsurgical therapy included bed rest, bracing, and physical therapy.³⁶ Mean follow-up time was 11 months, with only 43 (69%) of patients available for telephone interview at final follow-up. The surgical group achieved mild improvements in neurologic status compared to slight worsening in the nonsurgical group, and both groups demonstrated equivalent improvements in pain and satisfaction, though none of these changes achieved statistical significance. Further analysis of work and social components of functional assessments revealed statistically significant improvements in the surgical group, though these specific measures have not been externally validated. Kadanka et al. reported the results of a 10-year, prospective randomized trial of operative versus nonoperative management of CSM in a cohort of 64 patients with mild or moderate disease (mean JOA score ≥ 12).³⁷ Outcome measures included a modified JOA grading system and a 10 m walk time. Video assessments of patients performing activities of daily living were also performed, with grading by both blinded observers and the patients themselves. Of the 47 patients (73%) completing the 3-year follow-up period,

no statistically significant differences were seen between surgical and nonsurgical treatment groups with regard to any of the above outcome measures.

CONCLUSION

Cervical spondylotic myelopathy is a multifactorial disease process with an insidious onset and nonspecific symptoms that frequently lead to a delay in diagnosis. The natural history of CSM is generally that of stepwise decline in neurologic function, though extensive disease may increase the likelihood of catastrophic neurologic injury with otherwise minimal trauma. Risk factors for disease progression may include greater severity on presentation in combination with circumferential compression on imaging, though it remains difficult to predict a given individual's disease course on the basis of factors such as age, comorbidities, functional status, or imaging characteristics. For patients with mild or moderate symptoms, or for those in whom surgical treatment may be medically high risk, nonoperative treatment modalities such as analgesia, intermittent immobilization, or physical therapy may be reasonable options for symptomatic relief, though these are unlikely to modify the disease course. The decision to pursue medical or surgical treatment must be pursued on a case-by-case basis, incorporating the patient's specific complaints, life expectancy, quality of life, and perioperative risk factors. Additional randomized, prospective studies are needed to identify patients with CSM at risk for disease progression as well as those who may benefit most from early surgical intervention.

The anterior cervical discectomy and fusion (ACDF) is an effective method for treating patients with a variety of degenerative and post-traumatic conditions of the cervical spine. The goals of ACDF include pain relief, removal of neural compression, restoration of stability, and restoration or maintenance of disc height, foraminal space, and spinal alignment.¹⁻⁴

The anterior approach was developed in the 1950s; Dereymaeker and Mulier⁵ and Smith and Robinson^{6,7} introduced the currently common technique of ACDF. Cloward⁸ described a variation of the procedure using a bone dowel as opposed to a block of bone. In 1960, Bailey and Badgley described a fusion technique for patients with neoplasm and instability involving onlay strut grafts.⁹ Since then, an ACDF has been used to successfully treat cervical stenosis resulting from herniated discs, spondylosis, or ossification of the posterior longitudinal ligament (PLL). In the setting of multilevel spinal cord compression, various anterior decompressive options exist, including multilevel ACDF, corpectomy, and hybrid procedures. In multilevel ACDFs, neurological recovery is high¹⁰ with the consequence of decreasing union rates with an increasing number of levels treated.¹¹

SURGICAL RATIONALE

The prognosis for patients with cervical myelopathy is variable although most patients with cervical spondylotic myelopathy (CSM) experience a stepwise progression of their neurological dysfunction.^{12,13} Nonoperative management, including immobilization and periods of bed rest, has the potential to improve neurological symptoms.^{12,14,15} The majority of patients presenting with cervical myelopathy do not experience spontaneous improvement and instead deteriorate over time. Alternative therapies, such as epidural steroid injections, physical therapy, and non-steroidal medications, have not been shown to alter the natural course of the disease.¹² Manipulation should not be performed for the patients with CSM because neck extension can cause narrowing of the spinal canal.^{12,15} Several studies investigating patients treated conservatively have shown that approximately 26–50% of patients deteriorate neurologically over time.^{12,14,16,17} It is reported that 5% of patients deteriorate quickly, 20% have a gradual but steady decline in function, and 70% experience a stepwise progression of their symptoms with variable periods of quiescent disease.¹²

Nonetheless, several studies have reported that surgery can alter the natural history and change the prognosis of patients with CSM.^{18,19} Neurological improvement was seen in >90% of patients following either anterior or posterior decompression surgery, with neurological recovery ranging from 47% to 100%.²⁰ Recently, a prospective multicenter nonrandomized comparison of operative and conservative treatments for patients with CSM was reported.²¹ In this study, patients treated conservatively had significant worsening of their activities of daily living with progression of neurologic symptoms, whereas patients treated surgically experienced significant improvement in their functional status and neurological symptoms. Optimal results can be obtained when surgery is performed within 6 months to 1 year after the onset of symptoms in patients with mild myelopathy.²²

PREOPERATIVE IMAGING STUDIES

Patients with suspected cervical myelopathy undergo anterior-posterior, lateral flexion extension, and oblique X-rays. Radiographs can reveal spondylotic changes, such as narrowing of the disc space, osteophyte formation, listhesis, and narrowing of the osseous canal. If the sagittal diameter of the spinal canal is 12 mm or less, there is an increased risk of developing myelopathy.²³ The sagittal alignment of the cervical spine is an important factor for deciding on the surgical approach. Flexion-extension X-rays are necessary to evaluate ankylosed and unstable segments.¹⁵ Magnetic resonance imaging (MRI) is a useful modality for evaluation of the spinal cord.^{24,25} Magnetic resonance imaging demonstrates various compressive factors of the spinal cord, such as disc herniation, hypertrophy of the flavum, and PLL. Spinal cord compression can be assessed on both axial and sagittal images. High-intensity cord changes on T2-weighted images are often seen in patients with cervical myelopathy. Low-signal intensity on T1-weighted images is associated with poor prognosis for neurological recovery.²⁶

A conventional myelogram in flexion and extension is utilized to assess the dynamic factor in spinal cord compression.²⁷ A computed tomography (CT) myelogram provides information regarding the bony compressive factors, such as osteophytes and ossified PLL.²⁸ The computed tomography (CT) myelogram images are also useful in the planning of either anterior or posterior surgery.

DECISION-MAKING REGARDING THE SURGICAL APPROACH: ANTERIOR OR POSTERIOR

The choice of either an anterior or a posterior procedure for decompression of CSM is based on multiple factors, such as the location of the compressive pathology, the extent of the degenerative process, the sagittal alignment of the cervical spine, motion preservation, the presence of neck pain, previous operations, and the patient's age and medical conditions.²⁹⁻³¹ Generally, for cases in which the compressive pathology is ventral to the spinal cord, the majority of surgeons prefer an anteriorly based procedure.^{32,33} An anterior approach allows direct removal of the compressive pathology without manipulation of the cord. When kyphotic sagittal malalignment is present, anterior procedures may serve to improve cervical lordosis. The intervertebral arthrodesis may also have an effect on reducing pain arising from the spondylotic motion segment. Fusion of three or more motion segments is associated with a higher nonunion rate and graft-related problems when compared to one- or two-level procedures.^{11,34,35} For patients with greater than three levels of compression, a posteriorly based procedure such as laminectomy/fusion or laminoplasty is preferred.^{29,30,36} Posterior decompression and fusion is an option for patients with kyphosis,³⁷ although high complication rates associated with multi-level posterior fusions are reported.^{38,39} On the basis of the results from a systematic review comparing anterior and posterior procedures, anterior surgery had better clinical outcomes but also had more complications during the early postoperative stage.⁴⁰ At the middle to late stage, posterior procedures had similar clinical outcomes and complication rates to anterior procedures for patients with CSM. We previously conducted a prospective study comparing the anterior and posterior approaches for the treatment of CSM, and we reported that the anterior procedure provided a significantly better improvement of neurological symptoms, particularly in regards to improvement of the upper extremity motor function.⁴¹ We further evaluated the patients with poor outcomes following a posterior approach, and we found that the presence of a residual anterior compressive factor of the spinal cord after surgery can cause an insufficient decompression that is associated with poor outcomes.⁴² This residual anterior compressive factor may be predicted preoperatively by measuring the

Fig. 42.1: Surface landmarks for skin incisions: the hyoid corresponds to C3, the thyroid cartilage to C4-C5, and the cricoids to C6. An oblique skin incision may be used to fuse three segments or more.

distance between the anterior compressive factor and a midsagittal line connecting the midpoints of the spinal cord at C2 and C7 on MRIs taken before surgery.⁴³

PREOPERATIVE PLANNING

It is critical to evaluate a patient's preoperative respiratory function, as latent preoperative disorders may become symptomatic postoperatively secondary to retropharyngeal edema. Although smoking cessation at least 4 weeks before surgery has been shown to reduce the occurrence of perioperative respiratory and wound complications.⁴⁴ Patients should quit smoking entirely no later than 3 months before anterior cervical surgery because smoking delays bony union. Additionally, preventing provocation of symptoms (e.g. radiating pain to the arm in an extended position) is an important preoperative test for avoiding neural injury during surgery due to incorrect positioning of the neck. In highly stenotic patients, consideration should be taken to use spinal monitoring of transcranial motor-evoked potentials and somatosensory-evoked potentials.⁴⁵⁻⁴⁷

Procedure

The surgery is performed under general anesthesia. A roll placed lengthwise between the scapulae extends the head and neck. Excessive extension of the cervical spine is avoided when preoperative provocative symptoms are positive.

It is our preference to use a left-sided approach due to the more predictive course of the recurrent laryngeal nerve in the tracheoesophageal groove. However, literature suggests that the incidence of recurrent laryngeal nerve injury is not clinically significant when comparing a right- and left-sided approach. A transverse incision is made anterior to the appropriate interspace starting at the midline and extending laterally 4–6 cm. The skin incision level can be estimated from subcutaneous landmarks corresponding to the adjacent vertebrae. The hyoid corresponds to C3, the thyroid cartilage to C4-C5, and the cricoid to C6. An oblique skin incision may be used when three segments or more are being fused (Fig. 42.1).

The dissection is carried through the subcutaneous tissue to the platysma. The superficial cervical fascia is incised, and the interval between the trachea and the esophagus medially and the carotid sheath laterally is separated. The trachea and esophagus are retracted medially to expose the prevertebral cervical fascia overlying the bodies of the cervical vertebrae and the longus colli muscles (Fig. 42.2). Bilateral longus colli muscles are retracted, and retractors are set up carefully on these edges to avoid injury to the sympathetic plexus, esophagus, trachea, and carotid sheath (Fig. 42.3). Operating loupes with directed light or a microscope are used for the discectomy. The disc material is removed roughly with a pituitary rongeur, pituitary forceps, or a curette until the annulus becomes visible. The disks should be sufficiently curetted as far as the bilateral uncovertebral joints ensure accurate canal width and a symmetric decompression. This also ensures maintenance of the correct midline of the vertebral column during surgery. The cartilaginous endplates are removed from the superior and inferior surfaces of the disc space (Fig. 42.4). The posterior rims of the vertebral bodies are carefully trimmed to expose the posterior annulus and PLL. Osteophyte resection is performed by further trimming upward and downward from the posterior rims using a diamond burr (Figs. 42.5A and B). If needed, the PLLs are incised to expose the dura. After removal of the intervertebral disk, the upper and lower vertebral bodies are fused using a variety of graft materials, such as iliac crest autografts, fibula autografts, allografts, cages, and ceramics. Anterior plating is used to prevent graft dislodgment and to enhance the fusion rate. The wound is closed with absorbable sutures and sterilely dressed (Figs. 42.6A and B).

Fig. 42.3: Exposure of the anterior aspect of the cervical spine with bilateral longus colli muscle retracted.

Fig. 42.4: Discectomy: the intervertebral disks are curetted as far as the bilateral uncovertebral joints. The cartilaginous endplates are removed from the superior and inferior surfaces of the disc space.

Corpectomy, Hybrid Procedure, and Circumferential Fusion

An alternate method to improve fusion rates after multilevel decompressions is a corpectomy. In addition to improving fusion rates, a corpectomy provides a more extensive decompression. Since a corpectomy removes the entire posterior cortex, it is effective for conditions with stenosis posterior to the vertebral body. Stenosis at two adjacent levels can be decompressed with a single-level corpectomy compared with a two ACDF. For a two-level ACDF, there are four bone-graft interfaces compared with only two interfaces for one-level corpectomy. The risk of

pseudarthrosis is, therefore, generally less with corpectomy than with multilevel ACDF. Hilibrand et al. retrospectively compared 131 patients undergoing multilevel ACDF to 59 patients undergoing multilevel corpectomy.¹¹ The rate of nonunion was 34% in the multilevel ACDF, whereas 7% of nonunion cases were found in the corpectomy group. However, there were six cases with graft dislodgement, and four patients undergoing corpectomy required revision surgery. A systematic review comparing ACDF and corpectomy also revealed that the nonunion rate among patients who underwent ACDF was significantly higher than that of patients who underwent corpectomy for multilevel cervical spondylosis, while blood loss and

Figs. 42.6A and B: Lateral views of the X-rays following anterior cervical discectomy and fusion using iliac crest autograft (A) and hydroxyapatite spacer (B).

Fig. 42.7: Hybrid procedure of anterior cervical discectomy and fusion and corpectomy using hydroxyapatite spacer.

the rate of graft dislodgement in patients who underwent corpectomy were higher than patients who underwent ACDF.⁴⁸ In deciding between the two procedures, the risks associated with corpectomy, including more blood loss, graft dislodgement, and hardware failure, should be taken into account.⁴⁹ However, corpectomy may be considered preferable to multilevel ACDF, especially in higher-risk patients, such as recent smokers and diabetics, or in cases that require revision surgery.

Hybrid procedures of ACDF and corpectomy can also be applied for multilevel disease (Fig. 42.7). This hybrid procedure provides both sufficient decompression and maintenance of stability. Ashkenazi et al. reported the cases of multilevel disease that underwent the hybrid procedures of corpectomy and ACDF. In this study, all 13 patients achieved fusion without additional posterior instrumentation.⁵⁰ Anterior decompression with circumferential fusion is an option for cases of multilevel (three

or more) spondylosis or ossification of the PLL requiring extensive decompression and fusion. The major disadvantage of this method is greater invasion for the patients with prolonged operating time. However, the additional posterior fusion improves the fusion rate and decrease the incidence of graft-related complications.⁵¹

Graft Material

An autologous tricortical graft harvested from the iliac crest can provides excellent clinical results in achieving fusion.⁵² However, there are significant complications at the donor site with this method, including donor site pain, hematoma, infection, fracture of the ilium, sensory disturbance, and cosmetic disability.⁵³ In addition, the rate of complications is known to be higher following anterior harvest from the iliac crest compared to posterior harvest.⁵⁴ Because of the morbidity associated with autograft harvesting, alternative graft materials for ACDF have been developed.⁵⁵⁻⁵⁷ Fibula allograft is considered to be an excellent option, but the union rate is not as high as with iliac autograft.⁵² Furthermore, this allograft is not commercially available in some Asian countries, including Japan. Other options include titanium or polyetheretherketone (PEEK) cages, polymethylmethacrylate (PMMA), and an osteoconductive ceramic spacer including hydroxyapatite.^{55,58-61} Our recent experience with hydroxyapatite with percutaneously harvested iliac crest bone has been positive (Yoshii et al. 2013)⁶² (see Fig. 42.6). Bone morphogenetic proteins (BMPs) are an unrefined graft technology, and guidelines on dosage and delivery are currently being developed.⁶³ Although BMPs demonstrate impressive osteoinductive properties, they are currently hindered by significant cost constraints and complications.⁶⁴ Use of BMP in the anterior cervical spine is contraindicated secondary to its associated with postoperative swelling and significant airway complications. Other composite bone grafts present theoretical benefits; however, no consistent algorithm has been proposed. The cost of adjuvant therapies should also be taken into account.

Anterior Plating

Anterior cervical fusions were historically performed as stand-alone structural grafts and required prolonged bed rest or immobilization. Anterior cervical instrumentation was initially used in cases of cervical trauma. Indications for using plate fixation have been expanded over time to include degenerative cases. Hence, there has been a

progressive increase in the number of surgeries utilizing anterior cervical fusion and plating. Along with increased use of plating systems, plate designs have evolved over time. Orozco and Houet⁶⁵ described the use of a one-third tubular plate in the 1970s. Caspar developed a trapezoidal plate in the 1980s, and he used this plate for various indications, including trauma, tumors, and revision surgery.⁶⁶ Early devices required penetration of the posterior cortex of the vertebral body, which was associated with the risk of dural penetration. Furthermore, failure at the interface between the implant and host bone and subsequent graft dislodgement were frequently observed in multilevel fusion cases.⁶⁷ The second-generation systems featured screws fixed to the implant and permitted screw convergence on placement. The latest third-generation systems consist of dynamic semiconstrained plates that accommodate the normal settling of the graft, avoid stress shielding of the anterior column, and provide normal strut graft loads.⁶⁸

COMPLICATIONS

There are various complications related to the retraction and dissection of the vascular and nervous structures. Common complications are recurrent laryngeal nerve palsy, dysphagia, and wound hematoma. Recurrent laryngeal nerve injury occurs in 2–11% of patients, although the symptoms are often minor and resolve spontaneously.^{69,70} The mechanism includes direct injury, traction, edema, or tethering of the recurrent laryngeal nerve against the endotracheal tube.⁶⁹ Recurrent laryngeal nerve injury can be minimized using gentle tissue retraction. A left-sided anterior approach to the spine is recommended because the course of the recurrent laryngeal nerve is more constant on the left than on the right.⁷¹

Dysphagia is associated with retropharyngeal tissue edema from esophageal retraction or from plate prominence. The incidence of dysphagia is reported to be as high as 50% postoperatively, but this generally decreases over time.⁷² Postoperative dysphagia occurs more frequently in women and in cases of multilevel anterior fusion. The use of lower profile plates may decrease the risk for dysphagia.⁷³

The development of a postoperative wound hematoma is also common and is a potentially catastrophic complication. These present mainly as a neck mass associated with dysphagia, and occasionally with respiratory distress. The incidence of a postoperative hematoma is reported to be 1–11%.⁷⁴ Use of a drain is useful to decrease the risk of a postoperative hematoma.

C5 palsy is a well-recognized complication that can occur with either anterior or posterior cervical surgery. The incidence of postoperative C5 palsy following surgery for cervical compression myelopathy has been reported in an average of 4.6% (range 0–30%) of cases. The average incidences were 4.3% (range 1.6–12.1%) in cases of anterior decompression and fusion and 4.7% (range 0–30.0%) in cases of posterior decompression.⁷⁵ C5 palsy immediately following surgery is presumably due to direct injury to the nerve root.⁷⁶ The risk of neural injury is reported to be high in patients with ossification of the PLL.⁷⁷ In patients undergoing an anterior procedure, some authors have suggested that C5 palsy results from the kinking of the nerve root at the lateral part of the residual spur or ossified PLL.⁷⁵ Other authors have hypothesized that displacement of the graft makes the neural foramen narrow, thereby causing compression of the nerve root.⁷⁸ The clinical symptoms consist of deltoid weakness and radicular arm pain. Most patients can expect to experience a spontaneous recovery within 1 year.⁷⁵ It is critical to encourage passive shoulder range of motion to prevent a frozen shoulder.
